**Results:** The baseline HBP level between two groups showed no difference. Different to survival group, the HBP level of non-survival group decreased gradually. The clearance rate of 3-day HBP (HBPc-3d) and 7-day HBP (HBPc-7d) in survival group were significantly higher than those in non-survival group ($p < 0.001$). The area under the ROC of HBPc-3d (cutoff $\leq$ 43%) and HBPc-7d (cutoff $\leq$ 14%) was 0.857 and 0.890, respectively. The PCT and hs-CRP level had no correlation with dynamics of the HBP level.
**Conclusions:** The dynamics of plasma heparin binding protein level have a good predictive value for the 28-day prognosis of sepsis patients. The continuous increase of HBP level indicates poor prognosis.

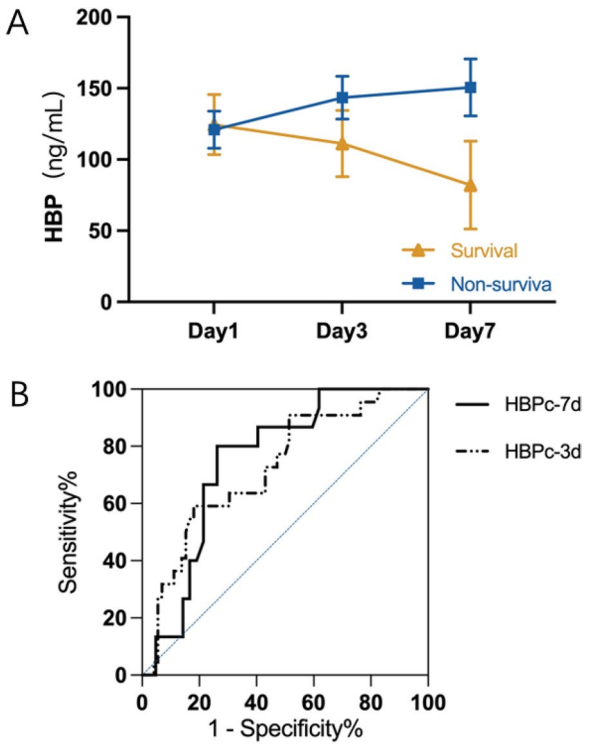

**Fig. (abstract 001160)** Dynamics and predictive value of HBP: A: There was no significant difference in the level of D1 HBP. The plasma heparin binding protein levels of D1, D3 and D7 in survival group decreased gradually, while the plasma heparin binding protein levels of D1, D3 and D7 in the death group increased gradually. B: The AUCs of plasma HBPc-3d and HBPc-7d predicting 28-day mortality of sepsis were 0.857 (95% CI 0.770–0.921) and 0.890 (95% CI 0.779–0.958), respectively

**Introduction:** Despite the need for new preventive and curative interventions in ventilator-associated pneumonia (VAP), very few have been evaluated and implemented in clinical practice in recent years. This may be partly due to the required VAP criteria used by regulatory authorities for the approval of interventions. Signs and symptoms for VAP diagnosis defined by the FDA, include hypothermia, hypotension, hypoxia or tachypnea, which are often irrelevant in the Intensive Care Unit (ICU), where these vital parameters are artificially controlled, while other eligible symptoms are non-specific (leukocytosis, purulent secretions, and fever).

**Objectives:** We hypothesise that FDA criteria could overestimate VAP diagnosis compared to clinical assessment by bedside physicians limiting the potential for future drug approval in clinical trials.

**Methods:** The European-wide Perpetual Observational Study on VAP (POS-VAP) [1] within ECRAID-Base prospectively enrolls patients under invasive mechanical ventilation (IMV), collecting routine clinical and microbiological data about VAP. Patients included in the study are over 18 years old and at risk of VAP, i.e. admitted to the ICU and under IMV for at least 48 h. The VAP population was defined as patients who met the FDA criteria for VAP diagnosis [2]. Clinical cure was defined as a combination of resolution of signs and symptoms present at VAP onset, survival and/or ICU discharge alive between days 7 and 10 from VAP diagnosis [3]. At ICU discharge, bedside physicians were asked whether they diagnosed VAP during the patients' stay. Completion of antibiotic treatment for VAP by day 10 in patients alive 72 h after the end of treatment was considered as physician-defined VAP resolution.

**Results:** From August 2022 to September 2023, 984 eligible patients provided informed consent and were enrolled, of which 228 patients had a FDA-defined VAP after a median of 7 [IQR 5–11] days of IMV. Overall, 22/228 FDA-VAP were not considered as VAP by clinicians, while 26/232 clinical VAP did not fulfill FDA criteria. Clinical cure was attained in only 22% ($n=50$) of FDA-VAP, whereas 47% ($n=107$) of FDA-VAP patients completed VAP-related antibiotic treatment within 10 days of VAP onset. Symptoms most frequently persistent in the non-cured population were leukocytosis 70% ($n=124$), purulent secretions 48% ($n=85$) and fever 42% ($n=74$).

**Conclusions:** Unlike our hypothesis, FDA-VAP correlated well with clinical-VAP diagnosis (10% discordance in both directions). However, FDA clinical symptoms underestimated clinical cure compared to treatment criteria (22% vs. 47%). Low clinical cure rates might be a reflection of VAP misdiagnosis, rather than treatment failure. Thus, new criteria are needed to improve the evaluation of VAP clinical cure in clinical trials. In-depth review of discrepant cases may help identify better criteria.

**Introduction:** Venous thromboembolism (VTE) is a serious complication of critical illness, and despite guideline-adherent thromboprophylaxis, the risk of VTE in critically ill patients remains substantial. Potentially, this is the result of thromboprophylaxis failure in patients at particularly high risk of VTE. Following this, a personalized assessment of VTE risk may facilitate patient-specific interventions and lower the risk of VTE in critically ill patients.
**Objectives:** We aimed to develop and externally validate a prognostic model for VTE in critically ill patients including known prognostic factors (the PROVE-IT model). Furthermore, we aimed to assess the external validity of existing models.
**Methods:** We included critically ill patients admitted to the intensive care unit (ICU), excluding patients with planned admissions, stays under 24 h, ages below 18 years, recent VTE, or therapeutic anticoagulation within 24 h of ICU admission.
The outcome was VTE after ICU admission as detected in clinical practice. Prognostic factors were selected from a recent meta-analysis. Multiple logistic regression was used to estimate model coefficients. The C-statistic was used to measure discrimination, calibration plots, the integrated calibration index (ICI), the E50, the E90, and the Emax were used to assess calibration. Decision curve analysis (DCA) was performed to evaluate clinical usefulness. Existing models identified by a literature search were externally validated for comparison.
**Results:** In total, 26.218 patients were included in the development cohort, and 1.983 were included in the external validation cohort. The PROVE-IT model incorporates predictors collected within 24 h of ICU admission, including central venous line placement, personal history of VTE, active malignancy, changes in body temperature, respiratory rate, lactate, white blood cell count, surgical ICU admission, use of vasopressors, mechanical ventilation, thromboprophylaxis, weight, heart rate, and mean arterial blood pressure.
The external validation of the PROVE-IT model yielded a C-statistic of 0.629, an ICI of 0.00664, an E50 of 0.00447, an E90 of 0.00131, and an Emax of 0.154. Upon external validation of an existing prognostic model, the ICU-VTE score, we found a C-statistic of 0.600, an ICI of 0.0119, an E50 of 0.0118, an E90 of 0.0251, and an Emax of 0.932.
Figure 1 illustrates the calibration of the PROVE-IT model and the ICU-VTE score. Upon DCA, it was found that the PROVE-IT model may yield a higher net benefit than default treatment strategies at risk thresholds of approximately 1–5%, though this did not reach statistical significance (Figure 2).
**Conclusions:** The PROVE-IT model performed well in the development cohort. In the external validation cohort, its performance was marginally worse but still promising. However, the PROVE-IT model exhibited unclear clinical usefulness upon DCA and is thus inadequate for clinical implementation. An existing prognostic model, the ICU-VTE score, exhibited inadequate performance as well. Accordingly, there is currently no appropriate method to assess individual risk of VTE in critically ill patients. Future research should focus on investigating novel prognostic factors to improve risk stratification and other means of improving the safety and efficacy of thromboprophylaxis in critically ill patients.

***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001163

**Introduction:** Cardiogenic pulmonary edema (CPE) occurs as a result of an increase in hydrostatic pressure at the capillary level, leading to impaired gas exchange and requirement for mechanical ventilation. This support can trigger a complex molecular response to mechanical stretch known as ventilator-associated lung injury (VALI), which may lead to extensive pulmonary fibrosis due to ineffective lung repair.
**Objectives:** Our main objective is to study the impact of mechanical stretch on different cell types and to identify the molecular mechanisms involved in lung repair during mechanical ventilation.
**Methods:** Bronchoalveolar lavage fluid (BALF) samples were obtained from patients undergoing either protective mechanical ventilation (tidal volume 6–8 ml/Kg, PEEP 5 cmH2O) or continuous positive airway pressure (CPAP) of 5 cmH2O. The impact of both conditions (cyclic stretching versus static) was evaluated using wound healing assays (Figure 1) with epithelial cells (BEAS-2B) and fibroblast (MRC5) supplemented with 10% of BALF. RNA was extracted from both cellular types in each experimental condition 24 h after wounding. RNA sequencing was performed and differentially expressed genes were identified with DESeq2. To analyze the molecular pathways involved and gene interactions, gene set enrichment analysis (GSEA) and STRING interaction database were used, respectively.
**Results:** Supplementation with BALF from patients undergoing cyclic stretch resulted in a slower wound closure rate in epithelial cells, compared to the static condition. Fibroblasts exhibited the opposite behavior, with proliferative response to cyclic stretch. A total of 154 and 583 genes with differential expression were identified, showing dysregulation in interleukin 6 (*IL6*) pathway in BEAS-2B and Leukemia Inhibitory Factor (*LIF*) pathways in MRC5. In addition, the epidermal grow factor receptor (*EGFR*) pathway was affected in BEAS-2B line (Figure 2).
Adding tocilizumab, an antagonist of *IL6* family members receptors, to BEAS-2B (Figure 1.B) and MRC5 (Figure 1.E) medium, reverted the differences between conditions, as well as amphiregulin (AREG), an *EGFR* agonist, in the epithelial line (Figure 1.C).
**Conclusions:** Tidal ventilation may promote a fibroproliferative response and a delay in epithelial-related lung repair. The transcriptomic response to mechanical stress indicates the implication of *IL6, LIF,* and *EGFR* pathways. Tocilizumab and amphiregulin could attenuate mechanical ventilation-associated lung injury.

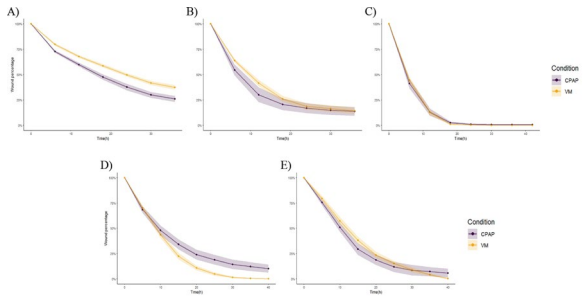

**Fig. 1 (abstract 001163)** Wound healing assays. A) BEAS-2B cell line wound healing supplemented with BALF from patients undergoing conventional ventilation compared to BALF from CPAP ($p$ value < 0.0001, repeated measures ANOVA) B), conditioned with tocilizumab (10 µg/mL) ($p$-value = 0.259, repeated measures ANOVA) C), conditioned with AREG (200 ng/mL) ($p$-value = 0.811, repeated measures ANOVA). D) MRC5 cell line wound healing supplemented with BALF from patients undergoing conventional ventilation compared to BALF from CPAP ($p$-value < 0.0001, repeated measures ANOVA) E), conditioned with tocilizumab (10 µg/mL) ($p$ value < 0.927, repeated measures ANOVA)

**Introduction:** Frail patients are increasingly recognized as a previously overlooked and vulnerable intensive care unit (ICU) population based on data from observational studies [1,2]. Data from randomized controlled trials on the representation and mortality of frail patients are missing. In addition, there are limited data on the association between frailty and clinical outcomes of patients with acute respiratory distress syndrome (ARDS), a syndrome with considerable attributable mortality [3].
**Objectives:** We aimed to estimate temporal trends of representation and mortality of frail participants in randomized controlled trials of ARDS.
**Methods:** We performed a secondary analysis of individual patient-level data from five ARDS Network and Prevention and Early Treatment of Acute Lung Injury (PETAL) Network randomized controlled trials (specifically: FACTT, ALTA, EDEN, SAILS, and ROSE) [4–8] published between 2006 and 2019. Based on requirement for everyday help (i.e., "assisted living") prior to hospitalization, which corresponded to a clinical frailty scale (CFS) of 5 or more, we categorized study participants into frail versus non-frail. We estimated the pooled representation of frail participants across trials of ARDS through proportional meta-analysis using inverse variance weights and random-effects. We estimated the representation of frail participants over time via a meta-regression analysis. Using a binary logistic regression model, we assessed the association between frailty and 90-day mortality after adjustment for age, sex, comorbidity, baseline oxygenation and baseline organ failures.
**Results:** Out of 3630 participants with ARDS included in our analysis, 701 (19.3%) were frail. Pooled representation of frail participants in clinical trials was 18.7% (95% confidence interval 14.8%-23.0%). Representation of frail participants in clinical trials increased over time ($p = 0.001$) [Figure], while their mortality remained stable ($p = 0.403$) and as high as 41%. Frail versus non-frail participants were older ($p < 0.001$), more likely to have aspiration as ARDS risk factor ($p < 0.001$), more likely to have at least one comorbidity ($p < 0.001$) and more likely to have cardiovascular ($p < 0.001$) or renal failure ($p = 0.007$) at baseline. Among non-survivors, end-of-life decisions did not differ between frail and non-frail ($p = 0.579$). Frail participants exhibited fewer ICU-free days ($p < 0.001$), fewer ventilator-free days ($p < 0.001$) and higher mortality (41.4% vs 26.8%, $p < 0.001$) than non-frail participants. Frail, as opposed to non-frail, participants were more likely to have subsequent disability.
**Conclusions:** In randomized controlled trials of ARDS, representation of frail participants increased over time, while their mortality remained stable and as high as 41%. Frailty was independently associated with poor clinical outcomes, including mortality, duration of organ support and subsequent disability, in ARDS.

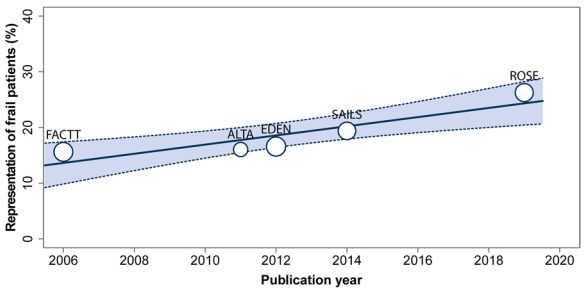

**Fig. (abstract 001165)** Representation of frail participants in randomized controlled trials of ARDS increased over time ($p = 0.001$)

**Introduction:** Invasive candidiasis including candidemia remains the most frequent invasive fungal infection in the hospital setting [1]. Moreover, mortality associated with invasive candidiasis is around 47% [1,2]. *C. albicans* remains the most common species causing candidemia, yet *non-albicans Candida* has been rising [2–4].
**Objectives:** To describe the epidemiology and outcome of candidemia in a cohort of critically ill patients.
**Methods:** This is a single retrospective study conducted from 2007 to 2020 in a University Hospital in Brussels, Belgium. All consecutive patients who were diagnosed with blood stream infection due to *Candida species* were included. A multivariate analysis was performed to assess risk-factors associated with mortality at 30 days.
**Results:** A total of 74 patients (64.9% males) were identified with a mean age of 59 (±14) years. The most frequent comorbidities were solid-organ transplantation ($n=23$, 30.7%), diabetes ($n=15$, 20.3%), chronic kidney ($n=15$, 20.3%) or liver diseases ($n=14$, 18.7%) and solid cancer ($n=14$, 18.7%). *C. albicans* and *C. glabrata* were the most frequent pathogens ($n=26$, 34.7% and $n=25$, 33.3%). There were no significant differences in common risk factors for candidemia between *C. albicans* and *C. non-albicans* infections. Central venous catheters ($n=7$, 35% vs. $n=13$, 65%) and intra-abdominal infections ($n=6$, 46.1% vs $n=8$, 61.5%) were the most frequent sources of candidemia for *C. albicans* and *C. non-albicans*, respectively. Resistance to fluconazole was present in 13 *C. non-albicans* isolates (27.1%). Echinocandin therapy was used in 15.4% ($n=4$) of infections due to *C. albicans* and in 31.2% ($n=15$) due to *C. non-albicans.* Mortality at 30 days was 46% (33/74), with 40% of cases directly related to candidemia. Mortality was similar across different *Candida* species (Fig. 1). In a multivariate analysis adjusted for source control, immunosuppression and Sequential Organ Failure Assessment (SOFA) score, *C. non-albicans* bloodstream infection was not independently associated with mortality.
**Conclusions:** In this cohort, *Candida non-albicans* was more frequently isolated in blood cultures than *Candida albicans*. The type of *Candida* isolate was not associated with 30-day mortality.

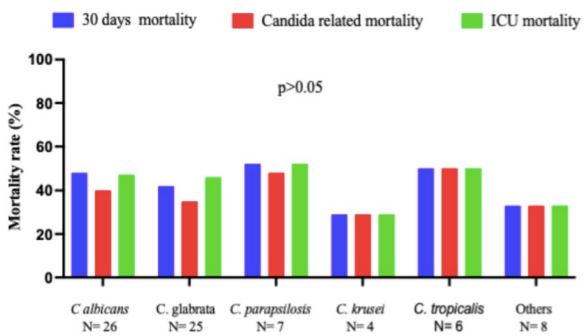

**Fig. 1 (abstract 00116)** Mortality rate according to different *Candida* species

### Conscious sedation during bronchoscopic procedures: Midazolam versus Ketamine

N. Z. Jaafar[1], N. Ben Slimene[1], A. Bayoudh[2], K. Ben Ismail[1], S. Temani[3], R. Sassi[3], F. Essafi[1], T. Merhabene[1]
[1]Intensive Care Unit, Regional Hospital of Zaghouan, Faculty of Medicine of Tunis, University Tunis El Manar, Tunis, Tunisia; [2]Pneumology Department, Regional Hospital of Zaghouan, Zaghouan, Tunisia; [3]Intensive Care Unit, Regional hospital of Zaghouan, Zaghouan, Tunisia
**Correspondence:** N. Z. Jaafar
***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001167

**Introduction:** Conscious sedation is a commonly used technique during medical procedures (diagnostic or therapeutic) that could be uncomfortable or painful. It allows patients to remain responsive to verbal and physical stimuli, keep the upper airways open with a spontaneous ventilation, and provide a certain degree of analgesia. It has been proven effective in various fields such as thoracic drainages or trans-esophageal echocardiograms, but its use remains limited during bronchoscopic procedures.
**Objectives:** To compare two methods of conscious sedation using midazolam and ketamine during bronchoscopic procedures.
**Methods:** This was a prospective interventional comparative bicentric study conducted in the intensive care unit (ICU) and the pneumology department of Zaghouan's regional hospital from September 2023 to March 2024. We included all patients over 18 years old who have an indication for bronchoscopic examination for diagnostic or therapeutic purposes.
Two groups were randomized in a 1:1 ratio as following: Group 1(G1): received conscious sedation with midazolam: the maximum dose was calculated at 0.05 mg/kg. Administration was by boli of 1 mg every 5 min. Group 2 (G2) received conscious sedation with ketamine at a dose of 0.3 mg/kg. All included patients underwent a medical consultation including a physical examination and a check for contraindications to midazolam or ketamine sedation prior to bronchoscopic examination. Oxygen therapy equipment and an emergency cart equipped with intubation materials, vasoactive drugs, and antidotes were available. During the procedure, patients were continuously monitored. All patients provided informed consent before the procedure.
**Results:** During the study period, 50 patients were enrolled. Gender ratio was 11.5. Median age was 66 [56–74] years in G1, and 61 [48–73] in G2. There were no significant differences in comorbidities: diabetes (8% vs 6%; $p=0.68$), chronic respiratory illness (22% vs 18%; $p=0.30$) and hypertension (14% vs 10%; $p=0.50$).

The main indications for bronchoscopy were transbronchial biopsies and the investigation of hemoptysis. Median doses used were 18 mg of ketamine [16.7–20.7] and 1 mg [0.75–1.75] of midazolam. Median duration of the procedure was 4 min [3–6] in G1 and 4 min [3–5] in G2. The operator expressed dissatisfaction regarding the use of midazolam compared to ketamine ($p = 0.04$) in terms of easiness. There was also a significant difference in the degree of sedation: patients in G1 were not adequately sedated according to the MOASS score ($p = 0.019$) and those in G2 experienced less pain referring to the EVA scale ($p = 0.01$).
There were no significant differences in observed adverse effects, except for tachycardia during the bronchoscopy which was more frequent with the use of ketamine ($p = 0.038$).
**Conclusions:** Both molecules shared a common goal ensuring the comfort and safety of patients throughout the medical procedure. Ketamine distinguished by its ability induce a state of sedation with a rapid and effective relief.

**Topic:** Sedation, analgesia and delirium

*Intensive Care Medicine Experimental* 2024, **12(suppl 1):**001168

**Introduction:** Clevidipine, the first third-generation calcium channel antagonist, has a rapid onset and offset of effect and reduces blood pressure (BP) by decreasing arteriolar resistance without affecting venous capacitance vessels.
**Objectives:** To present our experience with the use of Clevidipine in continuous infusion in critically ill patients for the control of arterial hypertension.
**Methods:** This is a retrospective, observational study conducted on patients admitted to critical care units of Hospital Gregorio Marañón in the year 2023. Epidemiological variables, comorbidities, severity scales, clinical characteristics, and complications were collected. Descriptive analysis of the sample was performed. Quantitative variables were expressed as mean (SD) if their distribution was normal or median (IQR) otherwise. Qualitative variables were expressed as percentages.
**Results:** A total of 26 patients were included, of whom 9 were women (34.6%) and 17 were men (65.4%), with a mean age of 57 ± 15 years. Upon admission, patients had a Charlson comorbidity index of 1 (± 2), SOFA (Sepsis Organ Failure Assessment) of 3 (± 5), APACHE II (Acute Physiology and Chronic Health Disease Classification System II) of 12 (± 6.25). Prior to Clevidipine administration, patients remained hypertensive for 4.5 h (± 19.75). The most frequent reason for admission was neurological, accounting for 57.7% of the total. 88.5% of the patients were medical, and only 11.5% of the sample were surgical patients.
65.4% of the patients had previously diagnosed arterial hypertension, of which 41% were taking 2 antihypertensive drugs as routine treatment, 29% were taking 1 drug, 17% were taking 3 drugs, and 5% were taking 4 drugs. 15.4% had diagnosed chronic kidney disease upon admission. The indication for Clevidipine was in 38% of neurological patients; in 15.4% were patients with hypertensive crisis with target organ damage; as the first option in non-surgical patients in 7.7%, and in 38.5%, it was used as rescue after failure with other drugs.
In 7 patients, it was used as the first option, accounting for 27% of the total. However, 2 drugs were tried in 34.6% (either bolus or infusion) and up to 4 drugs in 2 patients (7.7%).
The time required for infusion until achieving the target blood pressure was 120 min (± 232.5), the dose at which the target was achieved was 10 (± 15.25), with a total Clevidipine administration time of 20 h (± 34).
There was an incidence of arrhythmias of 11.5%, with atrial fibrillation being only 3.8%. The incidence of hypotension after starting Clevidipine was 31%, and patients developed hypertension after discontinuing Clevidipine infusion in 30% of cases. 65% did not experience hypertension rebound in the following 6 h after discontinuing the infusion. Of all patients, 46% were sedated. There were 19 patients on mechanical ventilation, with a median of 1 day of ventilation (± 16). ICU stay was 10 days (± 18). The mortality of these patients was 23%, with all deaths occurring in the Intensive Care Unit.
**Conclusions:** This study is a first approach to the use of Clevidipine in our unit, showing our experience since its inception. A more protocolized use will allow for better control of blood pressure in the future.

*Intensive Care Medicine Experimental* 2024, **12(suppl 1):**001170

**Introduction:** Inadequate lighting conditions in the intensive care unit (ICU) are supposed to promote chronodisruption and poor outcomes in critically ill patients [1]. A recent study has shown that light therapy could potentially reduce delirium incidence in ICU patients by modulating circadian melatonin rhythms [2]. However, light therapy, when applied through devices with a small light-emitting area, might not be effective due to the potential for causing stress through glaring effects [3,4].
**Objectives:** To evaluate stress levels under different lighting conditions in mechanically ventilated critically ill patients.
**Methods:** In a prospective, randomized controlled trial (NCT05556811), approved by the ethics committee of Charité Universitätsmedizin Berlin (EA4/104/22), we investigated stress levels as a secondary endpoint under bright-light therapy applied with a dynamic lighting system (DLS, VitalSky Advanced, Philips). Light intensity was determined using circadian effective irradiance (EC), calculated from spectral lighting data at the patient's eye level weighted by the action spectrum of melatonin suppression [5]. Mechanically ventilated patients expected to stay in the ICU for more than 5 days were included. Stress levels were assessed using the Distress Thermometer, a 0 to 10 visual analog scale [6]. They were measured once daily during the peak of EC (12 pm–4 pm) over four 24-h periods only for patients with a Richmond Agitation Sedation Scale (RASS) score greater than -4 and without delirium or subsyndromal delirium. Sixty patients were randomized into three groups, each exposed to a specific light scheduling algorithm (LSA, 1–3), a data-driven protocol designed to dynamically modulate the spectral composition and intensity of artificial lighting systems in alignment with human circadian rhythms. Group 1 (LSA-1) received high EC supplemented with episodes of blue-enriched white light (BAW-P). Group 2 (LSA-2) experienced high EC without BAW-P enhancement, while Group 3 (LSA-3), the control group, was exposed to lower EC similar to conventional hospital lighting. We compared the stress levels among these groups.
**Results:** Data from 42 patients were analyzed (LSA-1 $n = 13$, LSA-2 $n = 12$, LSA-3 $n = 17$). Stress levels were consistently low across all groups with different ECs. These preliminary results suggested that high EC (LSA-1, LSA-2) did not increase stress levels compared to lower EC (LSA-3). Patients in all groups experienced a pronounced decline in stress levels during the study period (Figure 1).
**Conclusions:** Bright-light therapy is feasible and may not significantly increase stress levels in ICU patients. This could be attributed to the technical features of the DLS, which emitted high EC from a large surface without entering the area of absolute glare. Additional data analysis and larger studies are needed to validate these findings.

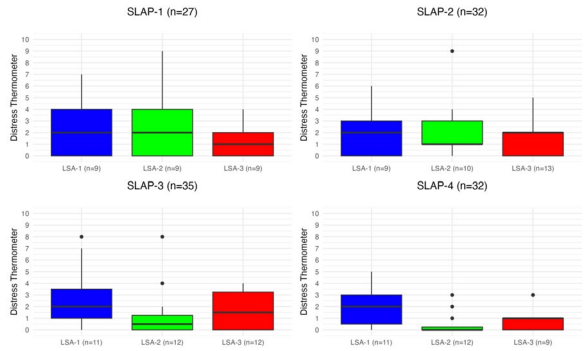

**Fig. 1 (abstract 001170)** Evaluation of stress levels in ICU patients once daily over four 24-h periods (SLAP, Stress Level Assessment Periods 1–4) using the Distress Thermometer. This assessment was conducted under a dynamic lighting system (DLS) using three different light scheduling algorithms (LSA-1, LSA-2, and LSA-3). LSA-1 involved high circadian effective irradiance (EC) with blue-enriched white light episodes (BAW-P); LSA-2 involved high EC without BAW-P; and LSA-3 simulated conventional hospital lighting with significantly lower EC, serving as the control group. Median, interquartile range (25th–75th percentile), and the 5th and 95th percentiles are reported

### Characterizing unplanned ICU admissions from surgical wards—a single center retrospective observational study

J. Pinto[1], C. Coutinho[2], D. Franco[1], J. M. Pereira[1], J. A. Paiva[1]
[1]Emergency and Intensive Care Department, São João University Hospital, Porto, Portugal; [2]General Surgery, São João University Hospital, Porto, Portugal

*Intensive Care Medicine Experimental* 2024, **12(suppl 1):**001171

**Introduction:** Unplanned referrals of surgical ward patients make up a sizable proportion of ICU admissions. Whether directly from the operating room, early in the postoperative period or during non-operative management, these patients may benefit from ICU admission for adequate resuscitation, advanced monitoring or organ support. In order to maximize patient benefit and resource management, clinicians should be aware of key factors that may predict ICU admission, length of stay (LOS) and mortality.

**Objectives:** To describe the population of patients with unplanned admissions to the ICU from surgical wards and evaluate their clinical outcomes.
**Methods:** We conducted a retrospective observational study of all patients admitted to a polyvalent intensive care unit between 01/01/2022 and 31/12/2023.
**Results:** From a total of 2432 individual admissions, 240 admissions (9.8%) were unplanned admissions originating from surgical wards. 168 patients (70%) had been emergency admissions and 72 (30%) had been elective admissions. Patients were mostly men ($n=152$; 63%), had a median age at admission of 70 (range 20–93), had a median Clinical Frailty Score of 3 (range 1–7), and had a median Charlson Comorbidity Index of 4 (range 0–15). Prior to ICU referral, patients had been admitted for a median of 4 days (range 0–170). Sepsis/septic shock was the most frequent cause of ICU admission ($n=93$; 39%), followed by hemorrhage/hemorrhagic shock ($n=25$; 10%). On ICU admission, the average SOFA score was 4.8 (range 0–15) and average APACHE II score was 14 (range 0–43). Subsequent average ICU length of stay was 5.4 days (range 1–40). 64 patients required IMV (26%) only; 33 patients (14%) required NIMV only; 17 patients (7%) required both; and 126 patients (52%) required neither. The pooled average duration of IMV/NIMV was 4.5 days (range 1–30). On follow-up, ICU mortality, 28 day mortality and in-hospital mortality were 10% ($n=25$), 14% ($n=33$) and 22% ($n=52$), respectively.
The presence of infection on ICU admission was significantly associated with ICU mortality, 28-day mortality and in-hospital mortality (OR 3.71 [95% CI 1.49–9.26], OR 2.51 [95% CI 1.17–5.38] and OR 2.74 [95% CI 1.45–5.17], respectively). Unplanned ICU referral following elective admission was also significantly associated with ICU mortality (OR 2.44 [95% CI 1.05–5.65]). Both the APACHE II score and the SOFA score were good predictors of ICU mortality (ROC-AUC 0.91 [95% CI 0.82–0.99] and 0.77 [95% CI 0.67–0.86], respectively). Gender and duration of IMV/NIMV were both significantly correlated with ICU LOS (Spearman-R 0.18, $p=0.006$ and Pearson-R2 0.17, $p<0.001$, respectively).
**Conclusions:** In addition to representing an important added workload in the ICU, unplanned ICU admissions from surgical wards for infectious complications and after elective hospital admission were independent risk factors for mortality. Strategies should be developed for the early identification of deteriorating patients in surgical wards.

**Topic:** Perioperative care

*Intensive Care Medicine Experimental* 2024, **12(suppl 1):**001173

**Introduction:** Acute kidney injury (AKI) is a frequent complication of critical illness. Persistent AKI, lasting more than 48 h from onset, is associated with increased morbidity and mortality compared to transient AKI which is reversed within 48 h. Timely recognition of patients with persistent AKI is crucial due to its poor prognosis and the potential effectiveness of prompt interventions in altering its course. Cluster of differentiation (CD)163 is a transmembrane molecule of macrophages and monocytes, that is cleaved in response to pro-inflammatory stimuli and tissue damage forming soluble CD163 (sCD163). sCD163 can be detected in the urine (uCD163) and is associated with sepsis-AKI.
**Objectives:** We hypothesize that CD163+ macrophages in the kidney might be associated with persistent renal injury in patients with AKI. The aim of this study was to investigate the predictive value of uCD163 for persistent AKI and renal recovery.

**Methods:** For the URIthmICS prospective cohort study, we collected urine samples and clinical data from adult patients acutely admitted to the ICU. Patients with chronic kidney disease or without a urine catheter were excluded from this study. AKI was defined based on the KDIGO criteria. uCD163 was measured by ELISA using the human sCD163 Duoset (DY1607) from R&D Systems. uCD163 concentrations were adjusted using urine creatinine levels to correct for the water content in the urine (cuCD163) and both parameters were used for the analysis.
**Results:** 104 patients were included: 68 (65%) men and 36 (35%) women. The median patient age was 62 years (IQR 49–71). 59 patients (57%) met the AKI criteria within the first 7 days of ICU admission: 25 patients (42%) with stage I, 16 patients (27%) with stage II, and 18 patients (31%) with stage III. Transient AKI was observed in 19 patients (32%), while persistent AKI was observed in 24 patients (41%). 14 patients were discharged from the ICU and 2 patients died within 48 h. The uCD163 levels at admission were higher in AKI patients compared to non-AKI patients (median: 371.5 vs 114.2 pg/ml, IQR: 131.5–1258.2 vs 28.7–466.1, $p = 0.01$). uCD163 was also associated with AKI severity during ICU stay. The median uCD163 in patients with AKI III, at the moment of maximum AKI stadium, was higher than those in patients with AKI I and II (median: 1518.1 vs 743.6 and 333.8 pg/ml respectively, IQR: 342.5–3175.6 vs 459.9–1283.6 and 161.8–655.8, $p = 0.04$ and 0.04, respectively). Median cuCD163 levels at the onset of AKI during ICU stay were higher in patients with persistent AKI than patients with transient AKI (median: 65 vs 31 ng/mmol, IQR: 36.2–333 vs 10.1–103.3, $p = 0.01$).
**Conclusions:** uCD163 levels at admission were associated with AKI onset during the first 7 days of ICU stay. Moreover, uCD163 levels were associated with AKI severity and cuCD163 levels at AKI onset with persistent AKI.

***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001174

**Introduction:** For noninvasive arterial pressure (AP) monitoring, when access to the upper arm is unavailable, the oscillometric cuff is frequently placed on the lower leg (1). Due to the invasive nature of arterial catheterization, it is often not the preferred option (2). Except during invasive procedures, patients are typically in a semi-recumbent position, meaning the lower leg is not at the level of the heart. This may introduce a substantial bias in AP readings compared to measurements taken at heart level (3). Only a limited number of studies have assessed the reliability of lower leg AP measurements compared to the invasive reference, and none have investigated how patient positioning affects AP readings (4,5).
**Objectives:** The objective of this prospective study was to assess the influence of patients' position (horizontal or semi-recumbent) on lower leg AP measurements.
**Methods:** This study received approval from the Comité de Protection des Personnes Ouest IV on July 4th, 2023, under the identification number RCB:2023-A01099-36, and was registered on clinicaltrial.gov (NCT06032169). Adult patients with a radial catheter and stable AP were eligible for inclusion. Patients were excluded if they had cardiac arrhythmia, contraindications to cuff placement, interarm asymmetry (mean AP > 5 mmHg), or required urgent treatment. The sequence of patient positions (supine horizontal followed by semi-recumbent, or vice versa) was randomly assigned. Three sets of simultaneous and consecutive noninvasive and invasive measurements were obtained in each position. The measurement error (noninvasive − invasive arterial pressure) was calculated for each pair. The bias, determined by the mean measurement error, was used to assess systematic measurement error (6). Statistical comparisons were conducted using the Fisher exact test, Student's t-test, and Wilcoxon test, with a significance level set at $p < 0.05$.
**Results:** Fifty patients from two intensive care units were enrolled (Table 1) between October and December 2023, resulting in the collection of 150 pairs of arterial pressure measurements for each position: horizontal (backrest angle 0° [IQR 0;0]) and semi-recumbent (40° [IQR 40;45]). Regarding mean AP, there was a greater ($p < 0.0001$) measurement bias in the semi-recumbent position (bias ± SD = + 13.3 ± 10 .5 mmHg) compared to the horizontal position (bias ± SD = + 3.8 ± 1 0.4 mmHg). This difference amounted to + 10 mmHg [95% CI: 8; 11].
For systolic and diastolic AP, the concordance between noninvasive and invasive readings was poor, particularly worsening when in the semi-recumbent position.
**Conclusions:** The patient's position significantly influenced the measurements of arterial pressure in the lower leg. In order to address this positional impact, we suggest consistently subtracting 10 mmHg from the indicated value of mean AP when measured in the semi-recumbent position.

**Table 1 (abstract 001174)** Patients' characteristics

| Variable | Patients (n = 50) |
|---|---|
| Main reason for admission to the ICU | |
| Post-operative care | 30 (60 %) |
| Coma | 4 (8 %) |
| Circulatory failure | 3 (6 %) |
| Renal failure | 1 (2 %) |
| Other | 12 (24 %) |
| Age (years) | 65 [53 ; 71] |
| Males | 37 (74 %) |
| SAPS II | 28 [20 ; 34] |
| Body mass index (weight [kg] height [m] $^{-2}$) | 26 [22 ; 28] |
| Mechanical ventilation | 9 (18 %) |
| Delay between arterial catheter insertion and measurements (days) | 1.5 [0.7 ; 2.7] |
| Catecholamines | |
| Norepinephrine (µg kg$^{-1}$ min$^{-1}$) | 0.10 [0.06 ; 0.20] N=14 (28 %) |
| Dobutamine (µg kg$^{-1}$ min$^{-1}$) | 2 [2 ; 2] N=4 (8 %) |
| Ongoing antihypertensive medication | 21 (42 %) |
| Heart rate (beats per minute) | 80 [72 ; 88] |
| Systolic invasive AP (mm Hg) | 136 [122 ; 148] |
| Diastolic invasive AP (mm Hg) | 65 [56 ; 72] |
| Mean invasive AP (mm Hg) | 88 [76 ; 96] |
| Circulatory failure [a] | 18 (36 %) |
| Septic shock & severe sepsis | 1 (2 %) |
| Cardiogenic shock | 7 (14 %) |
| Effects of mechanical ventilation & sedation | 8 (16 %) |
| Other | 2 (4 %) |

AP, arterial pressure. SAPS II, simplified acute physiology score II. ICU, intensive care unit.
Results are expressed as either median [interquartile range] or count (%).
a: Circulatory failure at the time of the measurements was defined by the presence of at least one of the following criteria: hypotension (invasive systolic SAP < 90 mm Hg and/or mean BP < 65 mm Hg), oliguria (< 0.5 ml kg h − 1) considered to be related to circulatory failure, arterial lactate > 2.5 mmol litre − 1, skin mottling, or vasopressor and/or inotropic drug infusion.

***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001175

**Introduction:** Hydrocephalus is a commons complication of subarachnoid haemorrhage (SAH) and intracerebral haemorrhage, which leads to poorer outcomes (1, 2). Several therapeutic strategies have been studied to improve patients' survival and functional status (3). Evidence suggests that removal of intraventricular haemorrhage leads to a reduction in the degree of hydrocephalus and consequent better outcome (2). Although it appears to be safe, intraventricular fibrinolysis (IVF) appears to lead to increased survivors' functional dependence (4).
**Objectives:** To evaluate the clinical outcomes and complications of patients treated with intrathecal alteplase for hydrocephalus.
**Methods:** Retrospective analysis of all patients treated with intrathecal alteplase along a one-year period from October 2022 to October 2023.
**Results:** Seven patients were treated (71% male), aged 32 to 77 y-o (median 56 y-o). The most frequent diagnosis on admission was intraparenchymal haemorrhage (4 patients, 57%) and 3 patients presented with SAH due to arterial aneurism rupture. Pre-admission modified Rankin scale (mRS) ranged from 0 to 3 (median 0). Considering SAH, all of them were classified as 4 in Fisher scale, Hunt & Hess scale ranged from 2 to 4 and World Federation of Neurological Surgeons ranking system ranged from 1 to 4. All patients had tetraventricular haemorrhage with hydrocephalus. On hospital admission, patients' Glasgow coma scale (GCS) ranged from 8 to 15 (median 10). Considering treatment, best medical care was implemented in all the patients and an external ventricular drainage catheter was surgically placed. Alteplase 1 mg was administered once in 4 patients, twice in 2 patients and 3 times in one of them. There were no immediate complications upon administration. One patient developed a ventriculitis due to Klebsiella pneumoniae, unrelated to alteplase administration (there was a negative cerebrospinal fluid culture in-between). No other infections were documented. Regarding patients' outcomes, 2 of them died (20 and 148 days after alteplase administration, unrelated deaths). No deaths were documented in the 6 months following hospital discharge. mRS in the 3–6 months period after discharge ranged from 2 to 5 (median 3). mRS 1 year after, was available in 3 patients and ranged from 1 to 4. The patient that scored 4 showed no improvement along the follow-up time (mRS 4 at 3–6 months follow-up) and the other 2 patients showed a reduction in 1 point in mRS.
**Conclusions:** Our data confirm the previously reported safety of IVF. Despite the limitation of the small number of treated patients, no complications were reported. Considering functional outcome, there is a reduction in mRS in 2 patients (3–6 months vs 1 year), but mRS did not return to baseline values. Our data are in line with previously reported series. IVF seems to be safe but further studies are required to prove its value in improving functional outcomes.

### Fluid resuscitation in ICU: Do we meet the guidelines?—a tertiary centre study

C. Morgado[1], F. A. Gonzalez[2], D. Batista[2], A. Fernandes[2]

***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001176

**Introduction:** Critically ill patients receive IV fluids in four forms: resuscitation, maintenance, replacement fluid, or nutritional 1. In the resuscitation phase, the therapeutic goal is rapidly reversing hypoperfusion by administering fluid boluses. A fluid bolus is the administration of a larger volume of IV fluid over a relatively short period, to increase intravascular volume and cardiac output. 1 According to NICE guidelines, resuscitation should be done with volume of 250 mL or 500 mL of crystalloids administered in 15 min. 2
**Objectives:** To acknowledge the practice of administering resuscitation fluids in an intensive care unit in a tertiary hospital.
**Methods:** We selected level II and III patients admitted to the Intensive Care Unit (ICU), between April 30th and June 30th of 2023. Every resuscitation fluid was justified in a prescription sheet and compared with the NICE guidelines during the first three days.
**Results:** We admitted 123 patients who needed level II or III care to the ICU for two months. From these, 41 patients required resuscitation fluids in the first 72 h of ICU admission, with 67 registered fluid bolus prescriptions. 56% were men, with an average age of 61 ± 17 years. Of the studied comorbidities, the most frequent were heart failure and chronic kidney disease. Most patients in need of resuscitation presented with septic shock at admission (39%).
Plasma-lyte was the most prescribed crystalloid (85%), followed by Ringer's lactate (4%) and normal saline (3%). Albumin was the preferred choice in 8% of cases.
The amount of fluid bolus prescribed was variable. Most physicians prescribed fluid bolus doses of 250 mL or 500 mL of crystalloid (26% and 42%, respectively). But 19% of prescriptions bolus were above 1000 mL.
Considering the duration of perfusion, 88% of the 250 mL volume dose was prescribed to be perfused in 15 min. On the contrary, only one 500 mL bolus was prescribed for 15 min. The remaining fluid boluses were done in 30 min (69%) or more (10%). 76% of fluid boluses were prescribed either for a longer time or higher volumes.
The most frequent justifications for fluid bolus were hypotension (44%), oliguria (19%), and tachycardia (18%). Although more than one reason could be selected, hypotension was chosen in 25% of prescriptions as the only justification.
In 99% of prescriptions, clinicians considered patients to be hypovolemic, evaluating clinical criteria only (1% considered normovolemic). Compared with NICE guidelines, resuscitation fluids were prescribed correctly for hypovolemic patients and the majority were with balanced solutions (Plasma-Lyte). Although the amount of fluid bolus was mostly well prescribed, only 24% of prescriptions were in the 15 min, suggested by the guidelines.
**Conclusions:** In this centre, resuscitation fluid bolus was prescribed according to the guidelines regarding volemic status, type of fluid and volume of fluid. However, the duration of bolus perfusion should be adjusted according to the guidelines and hemodynamic assessment should integrate beyond clinical evaluation.

***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001177

**Introduction:** Optimizing sedoanalgesia practice and detection of patients at risk of developing delirium is essential to reduce morbidity, mortality, improve patient comfort and reduce health care costs.
**Objectives:** The aims of this study were to unify criteria for the management of pain, sedation and delirium, within the safe practices developed in the ICU based on quality indicators of SEMICYUC (1), reduce patients complications, and increasing patient safety and well-being; implementing a protocol based on evidence-based Clinical Practice Guidelines for the management of sedoanalgesia and delirium in critically ill adult patients (2).
**Methods:** This is a prospective, observational study. During two-year period (January 22-December 23), the ICU quality group developed a protocol for the management and treatment of pain, sedation and delirium. We undertake a number of specific actions: a systematic review of the literature was carried out. The scales to be applied were evaluated (to assess: pain in patients who can communicate with Visual Analogue Scale (VAS), and in patients who cannot communicate with Scale of Behavior Indicators of Pain (ESCID); sedation with RASS scale, and Bispectral Index (BIS) during the use of neuromuscular blockers; delirium with Confusion Assessment Method for the ICU (CAM-ICU). A record of activities was elaborated and integrated into the ICU computer management system. We hold training sessions for ICU staff and checked the compliance with the protocol measures every three months. We monitored the following indicators of compliance with the protocol based on Quality Indicators of SEMICYUC, percentage of: professionals receiving formation; monitoring pain at least once every 8 h shift; evaluation of the level of sedation every 8 h in patients with mechanical ventilation and continuous sedation, and considering interruption of sedation daily; patients who receive neuromuscular blockers and are monitored with BIS; patients assessed for the presence of delirium and risk factors for developing it at least

once a day. Adverse events were registered. Finally, we confirmed compliance with treatment protocol. Clinical Practice Guidelines were applied to each patient admitted more than 24 h to the ICU in 2023.
**Results:** A total of 161 patients were admitted more than 24 h to the ICU in 2023, and were included in the study. All the equipment of the ICU received formation on the measures included in the protocol. 84 patients were on mechanical ventilation and there were 757 days of mechanical ventilation. 93% of non-communicative and 94% communicative patients were monitored for pain at least once every 8 h shift. 99% of sedated patients with mechanical ventilation the level of sedation was assessed every 8 h, and considered interruption of sedation daily. 100% of patients who received neuromuscular blockers were monitored with BIS. 93% of patients were evaluated for the presence of delirium and the risk of developing it at least once a day. There were only 12 device withdrawals. In addition, there was 95% of compliance with the treatment protocol.
**Conclusions:** The implementation of these Clinical Practice Guidelines has allowed the early identification of analgesia and sedation needs, and the prevention and identification of delirium, and has made it possible to unify management and treatment, increasing the quality of care and safety of patients admitted to the ICU.

### Views and barriers to achieving a Richmond Agitation Sedation Scale (RASS) score of zero in Adult Intensive Care Unit (AICU): a qualitative and quantitative survey

R. Tan[1], A. Whitehead[1], S. Mckechnie[1], J. Ede[1], E. Reynolds[1], A. Scisciani[1], A. Nair[1], C. Lisaba[1], S. Sutherland[2], M. Borthwick[1]

***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001180

**Introduction:** Sedation is used in mechanically ventilated critically ill patients for comfort and to facilitate care. However, deep sedation is associated with adverse effects such as increased mechanical ventilation duration and tracheostomy rate. Light sedation is recommended by international guidelines (Devlin et al., 2018), and is incorporated into OUH AICU's sedation policy (Tan et al., 2023). The proportion of AICU patients attaining the target RASS score of zero (unless contraindicated) is low.
**Objectives:** To explore the views and identify barriers faced by clinical staff in AICU when optimising mechanically ventilated critically ill patients' sedation target to a RASS score of zero.
**Methods:** An existing multi-professional sedation working team constructed a survey to investigate views and potential barriers towards good sedation practice. The survey used both qualitative and quantitative approaches utilising Microsoft forms as a data collection platform. The survey consisted of 8 to 10 questions, dependent on profession. The platform was piloted, and edited based on feedback received. The final survey was distributed to AICU doctors, pharmacists and nurses via email. Data collection ran for 10 days, two reminder emails were sent. Quantitative data were analysed using Microsoft Excel, qualitative data were analysed using thematic analysis (Braun and Clarke, 2022), with review by a second healthcare professional.
**Results:** The response rate was 53/201 participants. Respondents were doctors (9), pharmacists (3) and nurses (41). Overall, 30 were aware of the AICU sedation policy, and 17 stated they would always use it when caring for mechanically ventilated patients. Reasons reported for not using the policy included patient safety concerns, poor skill mix, and finding the policy to not be comprehensive enough. Some 34 respondents knew that the unit default RASS was zero. Out of 41 nurses, 15 nurses agreed or strongly agreed they had received enough guidance on sedation strategies during ward rounds. In addition, 6 doctors and a pharmacist felt somewhat confident or very confident formulating a sedation plan. Barriers to achieving a consistent default RASS included staff challenges with difficult to manage patients, operational challenges impacting sedation holds, and lack of confidence to perform sedation holds. More education, ward round guidance, and reinforcement of the unit's sedation policy were suggested as ways to improve sedation practice.
**Conclusions:** Despite evidence demonstrating benefits of light sedation and sedation holds, and an established unit sedation policy, there are still barriers to ensuring that AICU patients' sedation management is optimised. A programme of readily accessible education targeted at caregivers, rescue strategies for difficult-to-sedate patients and clear patient-specific strategies discussed at bedside during ward round are required.

**Introduction:** Vasopressin is recommended by 2021 Surviving Septic Shock guidelines (1) as second-line vasopressor for patients presenting hypotension refractory to norepinephrine. The proposed cutoff defining refractory hypotension ranges from 0.25 to 0.5 mcg/kg/min but there is no clear indication on the timing of introduction. Recent data (2–4) suggest that both norepinephrine threshold and timing of introduction can impact patient outcome. We conducted a meta-analysis of existing studies to evaluate the role of norepinephrine dose threshold and timing, respectively.
**Objectives:** To evaluate the role of norepinephrine dose threshold and timing on mortality in patients with septic shock.
**Methods:** We searched the PubMed, Cochrane, and Embase databases for randomized controlled trials (RCTs) and cohort studies from January 2000 to end of December 2023, according PRISMA guidelines. Research was restricted to studies in adult septic shock patients receiving vasopressin in addition to norepinephrine. Studies including subgroups data characterizing vasopressin introduction were identified. Primary outcome was defined as ICU, hospital or 28-day mortality.

**Results:** Sixteen studies were identified of which six of them used norepinephrine dose threshold and 10 using vasopressin timeline introduction to define "early" or "late" subgroups. The majority of studies were retrospectives studies with only 1 prospective randomised controlled trial (5), which included both information on dose and timing, 1 prospective cohort (13), the remaining being retrospective cohorts. Most studies (6–9) used dose threshold based upon the lower cutoff proposed by SCC 2021 guidelines (0.25 mcg/kg/min) with the exception of original VASST study 5 (15 mcg/min) and one study (0.4 mcg/kg/min) 10, while studies based upon timing used a timeline cutoff for vasopressin introduction ranging from 3 h up to 12 h from shock onset or vasopressor initiation (11–20). Early introduction based upon norepinephrine dose was associated with a OR value of 0.573 [0.475–0.691] $p < 0.001$; I2 = 62% while early introduction based upon timing was associated with a OR of 0.707 [0.597–0.839]; $p < 0.001$; I2 = 0%. The heterogeneity of the former subgroup was reduced (I2 = 0%) when removing the study which used a higher dose cutoff. The overall OR based upon 14 studies (2 studies using MIMIC data for dose or timing were removed to avoid double-counting) was in favor of early introduction of vasopressin with an OR value of 0.595 [0.503–0.705]; $p < 0.001$; I2 = 41.5%.
**Conclusions:** Early introduction of vasopressin, either based on lower norepinephrine dose or shorter time introduction, was associated with lower mortality. However, these results are mainly based upon retrospective cohorts and need to be confirmed by larger randomised controlled trials.

**Introduction:** Acute respiratory failure (ARF) is a frequently encountered critical medical condition, stemming from various underlying causes. The evaluation of diaphragm function using ultrasound has been gaining traction, serving as a valuable resource for offering supplementary anatomical and functional insights into numerous acute respiratory illnesses.
**Objectives:** To assess the performance of diaphragmatic ultrasound, by measuring different parameters (diaphragmatic excursion (DE), inspiratory time (IT), and thickening fraction (TF)) for predicting intubation during acute respiratory failure.
**Methods:** This is a prospective study conducted over nine-month period, in the ICU of Zaghouan's regional hospital, including patients presenting with acute respiratory failure. Diaphragmatic ultrasound was performed as part of the patient's initial examination prior to mechanical ventilation. The ultrasonographic examinations were performed by the same operator using a commercially available echocardiograph machine (Vivid T8). The function of right hemi-diaphragms was assessed by measuring diaphragmatic excursion (DE), inspiratory time (IT) and thickening fraction (TF). Measurements were made in a sitting position and were averaged from at least three different

respiratory cycles. Subsequently obtained ultrasound measurements and clinical parameters were recorded and analyzed. Two groups were identified: G1 = patients who did not need invasive mechanical ventilation (IMV) and G2 = use of IMV. Patients who had received mechanical ventilation prior to diaphragmatic ultrasound were excluded from the study.
**Results:** During the study period, 45 patients were enrolled. Mean age was 59 years [16–90]. Gender ratio was 6.5. Acute respiratory failure was, respectively, secondary to: community acquired pneumonia ($n = 23$), acute exacerbation of chronic obstructive pulmonary disease ($n = 10$), acute pulmonary edema ($n = 4$), pulmonary embolism ($n = 3$) and post-traumatic pulmonary contusion ($n = 3$), acute asthma exacerbation ($n = 1$) and respiratory distress syndrome secondary to acute pancreatitis ($n = 1$). Among the 45 patients, 18 required IMV. Intubation occurred with a mean delay of 3 days ± 1. When comparing the two groups, patients who did not require invasive mechanical ventilation were younger (55 ± 16 vs 65 ± 8; $p = 0.008$), had fewer comorbidities and lower severity scores (APACHEII (8 ± 5 vs 15 ± 5; $p = 0.000$), SAPSII (36 ± 15 vs 23 ± 10; $p = 0.008$). By comparing ultrasound measurements between the two groups, we noted that DE was greater in G1 (2 cm [0.8–3.6] vs 1.9 cm [0.8–3.75]; $p = 0.74$) and IT was longer in G1 (0.79 s [0.40–1.6] vs 0.6 s [0.3–1]; $p = 0.028$). TF was higher in G1 (24.6% vs 38.2%; $p = 0.008$).
**Conclusions:** Diaphragmatic ultrasound seems a promising tool for predicting outcomes in patients with acute respiratory failure; however, further studies with large number of patients are needed to validate its efficiency.

**Topic:** Acute respiratory failure and mechanical ventilation

**Introduction:** Intensive care medicine demands a high level of both technical and non-technical skills; traditional teaching methods may not be sufficient to prepare resident physicians adequately. Simulation has been established as an educational tool that allows for the acquisition and practice of skills in a controlled and safe environment.
**Objectives:** To implement simulation as a teaching methodology and integrate it into the curriculum for resident training.
**Methods:** A training program for intensive care residents was established at Vall d'Hebron University Hospital in Barcelona, a tertiary care facility. The program accepts three residents annually over a five-year period. An assessment was performed to identify competencies suitable for training with simulation as the methodology. Scenarios were developed based on the classifications of simulation zones. Zone 1 workshops focused on acquiring instrumental technical skills. Zone 2 introduced low-fidelity scenarios to provide a clinical context, while Zone 3 aimed to develop non-technical skills such as teamwork, situational awareness, and leadership. The module selection was guided by the "Competency-based Training in Intensive Care Medicine in Europe" (CoBaTriCe) initiative. Learning objectives were tailored to each year of residency. Six modules were meticulously designed to comprehensively cover the curriculum.

| | |
|---|---|
| SimZone 1—technical skills | Central line placement airway management EEG basic interpretation |
| Sim Zone 2—technical with clinical context | Asynchronies identification and treatment |
| Sim Zone 3—technical and non-technical skills | Approach to the patient in shock approach to the neurocritical patient<br>1. Approach to the patient with acute respiratory failure<br>1. Sedation, analgesia, and delirium management |

**Results:** Sessions took place in the advanced clinical simulation center during the academic year 2022–2023. In versatile classrooms, and in a box set up as an ICU for high-fidelity scenarios. Each scenario lasted 1 h, with two scenarios per session, held once a week every 15 days, with a maximum of 6 residents per scenario. Sessions were designed and led by intensivist trained as simulation instructors. In total, 25 sessions were conducted, totaling 50 training hours. R1 and R2 residents participated in modules on technical instrumental skills, attending 9 sessions (18 h of training); R2–R3 residents participated in 8 sessions (16 h); and R4 and R5 residents had 8 sessions designed for their learning objectives. Competency acquisition was assessed using checklists and evaluation rubrics at the end of scenarios. Upon completion of the training course, a satisfaction survey was conducted, completed by 14 residents. 100% of the residents stated that the practical activities were suitable and beneficial for learning, and they would recommend the program to other residents.
**Conclusions:** The implementation of a simulation-based curriculum is feasible in a tertiary hospital and has a high level of acceptance among residents.

**Introduction:** In recent years, the concept of acute-on-chronic liver failure (ACLF) has emerged. It is important to note that the severity of patients developing ACLF can vary; some studies have shown that up to 20% of patients with ACLF grade 3 can improve or resolve their condition.1,2 Therefore, it is crucial to consider admitting these patients to the ICU or at least evaluating them by the ICU team for the management of such organ failures. Initial severity, rather than the underlying disease, has been described as determining the prognosis of patients

with ACLF in the ICU. Recent studies have revealed that mortality and length of stay in the ICU for these patients are comparable to those of ICU-admitted patients without chronic liver disease but with equal severity of critical illness.3 In this context, it is essential to examine demographic characteristics, organ failures, and relevant differences between patients with chronic liver disease who were consulted with the ICU and those who were not during the years 2022 and 2023 in our center.

**Objectives:** To determine differences between patients with acute decompensations of liver cirrhosis admitted to the digestive ward that are consulted with ICU and those who are not.

**Methods:** This is a retrospective study on a cohort of patients with cirrhosis admitted to the ward due to acute decompensation during the years 2022 and 2023 ($N=318$). Differences between patients who were consulted with the ICU ($N=36$) and those who were not ($N=282$) were studied. Descriptive study of patients' demographic characteristics, severity scales, and organ failures (hemodynamic, respiratory, renal, and neurological). Comparative analysis by groups. Multivariate logistic regression model, model discrimination capacity assessed by AUC.

**Results:** A total of 318 patients were admitted to the ward, of which only 36 were consulted with ICU (11.3%). The mean age of the patients was 64.52 (SD ± 12.40). In univariate analysis, significant differences were observed between age, presence of ACLF, and organ failure between both the groups (Table 1). A multivariate logistic regression model was performed, including age < 75 years, female sex, respiratory failure, neurological failure, ACLF > 1 at admission, which showed high discriminative capacity to determine which patients were consulted with ICU (AUC 0.8, 95% CI 0.714–0.887).

**Table 1 (abstract 001185)** Demographic and clinical characteristics of study population ($n=318$)

| Variables | Total 318 ($N=$) n% | UCI consultation (36) 11,3 | NO UCI consultation (282) 88,7 | *P* value |

*Intensive Care Medicine Experimental* 2024, **12(suppl 1):**001187

**Introduction:** The level of evidence on the management of patients admitted to intensive care unit (ICU) for severe diabetic ketoacidosis (DKA) is low to moderate, as indicated by the current British and American recommendations (1, 2).

**Objectives:** The aim of this survey was to get an up-to-date picture of the management of patients admitted to ICU for severe DKA.
**Methods:** International survey endorsed by the European Society of intensive Care Medicine disseminated worldwide. The survey consisted of 24 items divided into 3 parts: (i) baseline characteristics of respondents and criteria for admission to ICU, (ii) modalities of the various aspects of management and (iii) biological monitoring. All items were selected according to the different areas of uncertainty and research identified from current international recommendations. One response per intensivist was expected.
**Results:** Overall, 522 intensivists from 57 different countries responded to the survey: 295 (57%) worked in Europe, 86 (16%) in North America, 25 (5%) in South America, 52 (10%) in Africa, 52 (10%) in Asia and 12 (2%) in Australia, 72% of intensivists worked in a teaching hospital and 39% of them worked in an ICU treating > 20 patients with severe DKA per year. The criterion for admission to ICU was pH for 362 (69%) intensivists with a threshold < 7.20, while ketonemia, blood glucose level and insulin dose were not used as criteria for admission to ICU for 486 (93%), 509 (97%) and 258 (49%) intensivists, respectively. Concerning fluid resuscitation, 290 (56%) intensivists had a dedicated protocol, 135 (26%) administered saline exclusively, 176 (34%) balanced solution exclusively, 153 (29%) both types of solution and 154 (30%) administered sodium bicarbonate. Concerning insulin therapy, 355 (68%) intensivists had a dedicated protocol, 228 (44%) administered an initial bolus, 221 (42%) used a fixed dose of 0.1 UI/kg/h and 159 (30%) titrated the insulin dose to the patient's blood glucose level. Intravenous insulin therapy was started as soon as the patient was admitted to ICU by 230 (44%) intensivists, after initial fluid resuscitation by 147 (28%) intensivists and after potassium supplementation in the event of kalemia < 4.5 mmol/L by 84 (16%) intensivists. Intravenous insulin dose was reduced as soon as blood glucose level was < 10 mmol/L by 159 (30%) intensivists, when ketones disappeared by 243 (57%) intensivists, 12 h after ketones disappeared by 45 (8%) intensivists and 24 h after ketones disappeared by 14 (3%) intensivists. Concerning biological monitoring, 394 (75%) intensivists routinely performed blood gases to manage severe DKA, which were arterial blood gases in 42% of cases.
**Conclusions:** The management of patients with severe DKA remains heterogeneous across the world, both in terms of fluid resuscitation and insulin therapy. These results will support future randomized clinical trials especially on the management of fluid resuscitation and the nature of fluids to use in these patients.

**Correspondence:** G. J. Posadas Pita
***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001188

**Introduction:** Hydric management in critically ill patients poses a complex aspect in routine practice within Intensive Care Unit (ICU), often regarded as challenging [1]. This complexity arises from the intricate and dynamic pathophysiology of our patients, influenced by multiple factors, notably including the inflammatory and nutritional status [2], [3]. Consequently, currently, we lack sufficient evidence to define a duration or quantity of fluid overload (FO) detrimental to patient prognosis.
**Objectives:** To determine the influence of inflammatory and nutritional markers during admission on fluid overload (FO) during ICU stay, analytical values were collected upon admission, on the 7th and 14th days. Acute inflammation was indicated by C-reactive protein (CRP) levels > 100 mg/L, persistent inflammation by Ferritin (FRT) levels > 1000 ng/mL, and nutritional status by prealbumin (pALB) levels < 15 mg/dL. In addition, FO was defined as an accumulated fluid balance (AFB) > 2000 ml upon ICU admission, while on the 7th and 14th days, it was defined as an accumulated weight-adjusted fluid balance (AFB) exceeding 10% of the patient's weight at ICU admission.
**Methods:** Single-center retrospective cohort study of patients admitted for more than 14 days for any reason to a polyvalent ICU between January 2022 and December 2023. Clinical and demographic data were recorded. Logistic regression analysis was performed to correlate fluid overload (FO) with CRP, FRT, and pALB collected upon admission, on the 7th and 14th days post-admission.
**Results:** A total of 146 patients were included, with 77.4% being male. Admission reasons were respiratory in 34.2%, neurological in 28.7%, infectious in 23%, cardiac in 7%, polytrauma in 15%, and digestive in 4.1% cases. The mean APACHE-II score upon admission was 14 (1–31).
The patients presented levels of pALB, CRP, and FRT at admission, 7th day, and 14th day of 17.3 mg/dL (2–26 mg/dL), 18.9 mg/dL (1–1200 mg/dL), and 19.1 mg/dL (3–49 mg/dL) for pALB; 96.7 mg/L (0–650 mg/L), 111 mg/dL (0–352 mg/L), and 95.7 mg/dL (0–633 mg/dL) for CRP; and 1061 ng/dL (3–23,000 ng/dL), 772 ng/dL (50–7200 ng/dL), and 1041 ng/dL (11–14,000 ng/dL) for FRT.
The logistic regression values are shown in Table 1.

**Table 1**

| | Crp-admission OR (IC-95%) p | FRT—14 d OR (IC-95%) p | pALB—7 d OR (IC-95%) p |
|---|---|---|---|
| FO 24 h | 2.2 (1.1–4.7) p 0.03 | 1.28 (0.6–2.7) p 0.5 | 0.6 (0.3–1.2) p 0.32 |
| FO 7 d | 2.8 (1.4–5.8) p 0.06 | 1.7 (0.8–3.6) p 0.15 | 0.45 (0.2–0.9) p 0.03 |
| FO 14 d | 2.2 (1.1–4.4) p 0.03 | 2.1 (1.0–4.4) p 0.03 | 0.7 (0.3–1.4) p 0.3 |

**Conclusions:** A CRP level > 100 mg/L upon admission, indicative of acute inflammation, is an independent risk factor for fluid overload (FO) throughout the admission.

- An FRT level > 1000 ng/mL on the 14th day, indicating chronic inflammation, is an independent risk factor for elevated FO on the 14th day of admission
- A low pALB level as a marker of malnutrition on the 7th day is an independent risk factor for FO on the 7th day.

***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001189

**Introduction:** Systolic dysfunction occurs in different pathologies in the Intensive Care Unit, the most frequent being septic cardiomyopathy, ischemic heart disease, and chronic congestive heart failure, requiring the administration of inotropes to improve cardiac function and patient survival. Following the administration of inotropes, the impact on the decrease in extravascular lung water Index (EVLWI) will be evaluated, since a value > 10 mL/Kg has been correlated with an increase in mortality; this decrease is achieved after the improvement of the filling pressures of the left cavities, according to the primary pathophysiology of these diseases.

**Objectives:** To describe the changes in EVLWI measurements by thermodilution following the administration of inotropic agents in patients with systolic dysfunction.

**Methods:** This is a observational, cross-sectional, and prospective analytical study. Five patients with a diagnosis of systolic dysfunction were evaluated, requiring an inotropic agent (Levosimendan) and placement of minimally invasive monitoring for transpulmonary thermodilution (Edwards Lifesciences®). Ultrasonographic measurements of systolic function were performed: LVEF (Left Ventricular Ejection Fraction), FS (Fractional shortening), TVI (time-velocity integral), SV (Systolic Volume), CO (Cardiac Output), and MAPSE (Mitral Annular Plane Systolic Excursion) and the EVLWI value was obtained by thermodilution. Friedman test was performed, evaluating the doses of 0.05 mcg/kg/min, 0.1 mcg/kg/min, and 0.2 mcg/kg/min for 24 h.

**Results:** Of the total of patients evaluated, four of them were female and the main diagnosis was septic shock of abdominal origin plus septic cardiomyopathy (60%). A decrease in EVLWI and the use of inotrope was evident in these patients with systolic dysfunction ($p < 0.05$) (Figure 1).

In addition, the administration of inotrope agents was correlated with the systolic function variables, demonstrating an increase in LVEF ($p = 0.016$), FS ($p = 0.016$), and SV ($p = 0.03$) following the administration of levosimendan, but not for the remaining of the variables (TVI, CO, and MAPSE) (Table 1, Figure 2).

**Table 1 (abstract 001189)** Systolic function variables in relation to the administration of Levosimendan

| Variable | 0.05 mcg/kg/min | 0.1 mcg/kg/min | 0.2 mcg/kg/min | *P*-value |
|---|---|---|---|---|
| LVEF | 33 ± 10 | 42 ± 11 | 44 ± 9 | 0.016 |
| FS | 22 ± 3 | 27 ± 3 | 33 ± 2 | 0.007 |
| TVI | 17 ± 5 | 20 ± 7 | 19 ± 6 | 0.247 |
| SV | 44 ± 19 | 50 ± 24 | 52 ± 20 | 0.03 |
| CO | 3.1 ± 1 | 3.6 ± 1 | 3.8 ± 1 | 0.143 |
| MAPSE | 14 ± 1 | 14 ± 1 | 15 ± 5 | 0.165 |

As part of the treatment of systolic dysfunction, medications that could alter the EVLWI, such as the use of loop diuretics, did not generate any modification, however, it is necessary to increase the sample number for a more detailed analysis.

**Conclusions:** It was determined that the use of levosimendan decreases the EVLWI value and improves some variables of systolic function using ultrasonography; however, in this study, an association with mortality could not be established due to the sample size. It is important to highlight that the lack of availability of resources in Intensive Care Units in Latin America limits the combined use of ultrasonography and transpulmonary thermodilution, with the latter monitoring being one of the most accurate methods of measuring EVLWI. Nevertheless, large samples are needed to elucidate the role of other variables that may contribute to the success or failure of the hemodynamic support.

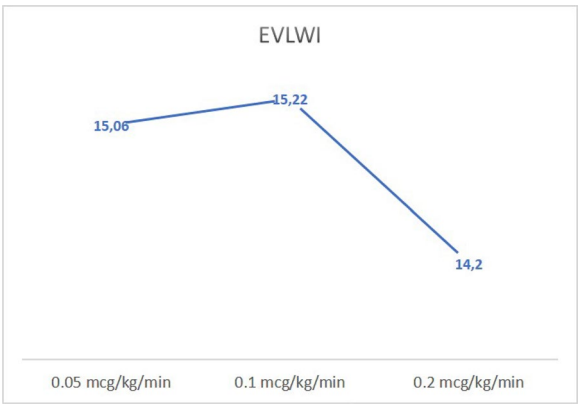

**Fig. 1 (abstract 001189)** Mean EVLWI at different doses of levosimendan ($p < 0.05$)

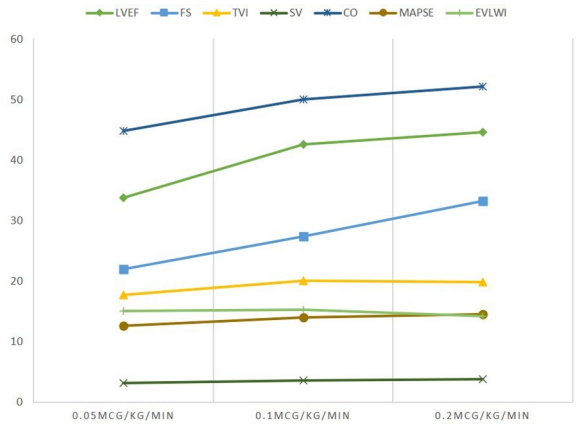

**Fig. 2 (abstract 001189)** Mean systolic function variables and EVLWI related to levosimendan doses

### Venous excess ultrasound score (VEXUS Score) for prediction of acute kidney injury (AKI) in critically ill septic patients: a prospective observational study

B. R. Ray[1], G. Mittal[2], D. Shende[3]
[1]Anaesthesia, Pain Medicine & Critical Care, All India Institute Of Medical Sciences, New Delhi, New Delhi, India; [2]Anaesthesiology, Pain Medicine and Critical Care, All India Institute Of Medical Sciences, New Delhi, India; [3]Consultant/Professor Dept. of Anaesthesia, Critical Care AIIMS, All India Institute Of Medical Sciences, New Delhi, New Delhi, India

***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001190

**Introduction:** Despite significant improvement in therapeutics over the decades, the mortality and morbidity associated with sepsis-induced AKI remain high. Increased venous pressure has been suggested as one of the in the culprit in the pathogenesis of AKI. Over the past decade, renal Doppler ultrasonographic parameters like renal resistive index (RRI) has provided insights into changes in the blood flow profile of the intrarenal arcuate or interlobar arteries. Recently, VEXUS Score was proposed to quantify the systemic congestion, which is also a promising tool for assessing kidney congestion. However, the correlation between VEXUS and AKI has not been evaluated in patients of sepsis or septic shock.
**Objectives:** The primary objective of study is to examine the correlation between serial VEXUS scores and AKI in patients with sepsis or septic shock. We also try to evaluate the impact of adding RRI to the VEXUS score in terms of sensitivity for predicting AKI. The relationship between VEXUS score and the need for renal replacement therapy (RRT), length of ICU stay and mortality were also evaluated.
**Methods:** Forty patients, age > 18 years, with a diagnosis of sepsis or septic shock (Sepsis 3 criteria), were included in this study. The components of the VEXUS score and Renal RRI were obtained serially on day 0 (upon admission to the ICU), 2, 3, and 5 after admission. In addition, clinical and laboratory data were collected to find out the onset of AKI.
**Results:** Twenty-three patients (57.5%) developed AKI as per the KDIGO guidelines. VEXUS, Modified VEXUS, RRI, all exhibited a significant positive correlation with the development of AKI. The combination of VEXUS and RRI displayed the highest correlation with a correlation coefficient of 0.74. Combination of VEXUS and RRI provided the highest AUROC (0.861), indicating its superior predictive value for AKI development. VEXUS score did not have any correlation for the requirement of RRT, duration of ICU stay, and 28-day mortality. The VEXUS score (grade 2/3) exhibited changes with a mean duration of 30.78 ± 16.97 h before any discernible change in creatinine levels, reflecting the onset of acute kidney injury (AKI).
**Conclusions:** The VEXUS score at ICU admission demonstrated a reasonably predictive capability for the development of AKI in septic patients, providing valuable lead time for intervention. Furthermore, the addition of the renal resistive index (RRI) to the VEXUS score improved its sensitivity while maintaining a reasonable level of specificity.

**Introduction:** Diaphragmatic dysfunction is identified as the main cause of weaning failure.
Recently, evaluation of diaphragmatic contractile structure and function using ultrasound during spontaneous breathing trial (SBT) has been used to guide weaning from invasive mechanical ventilation (IMV).
Its role in predicting weaning difficulties has not been clearly demonstrated, and its contribution compared to standard methods is still debated.
**Objectives:** To evaluate the use of diaphragmatic ultrasound in predicting respiratory weaning failure.
**Methods:** It was a prospective study conducted in the ICU of Zaghouan's regional hospital between January 2023 and March 2024. We included all the patients who responded to the criteria of weaning from IMV.
Diaphragmatic ultrasound was carried out in a semi-recumbent position (30°) at 30 min onset of SBT. Diaphragmatic function was evaluated by measuring diaphragmatic excursion (DE), diaphragmatic thickening (DFT) and inspiratory time (Ti). Echographic parameters were averaged from at least three different respiratory cycles. Subsequently obtained ultrasound measurements and clinical parameters were recorded and analyzed.
Weaning failure was defined as the reintroduction of mechanical ventilation within 48 h following extubation.
A DE < 10 mm and/or DTF < 30% were considered to define diaphragmatic dysfunction but does not impact the decision of extubation.

Secondary, two groups were identified and compared: Group 1: successful weaning from IMV; Group 2: failed weaning from IMV.
**Results:** During the study period, 39 patients were included. Median age was 52 years [35–52] and gender ratio was 2.5.
The main indication for IMV was acute respiratory failure secondary to community-acquired pneumonia ($n=3$), acute exacerbation of chronic obstructive pulmonary disease ($n=7$), acute pulmonary edema ($n=2$), post-traumatic pulmonary contusion ($n=3$) and acute asthma exacerbation ($n=4$). Weaning was initiated within a median period of 6 [4–9] days.
Among 39 patients, 24 patients were successfully extubated.
Patients were younger in group 1 (44 vs 62 years, $p=0.001$), had fewer comorbidities such as chronic obstructive pulmonary disease ($n=2$ vs $n=5=$, $p=0.08$) and lower IGS II and APACH II scores ($p=0.036$ and $p=0.003$, respectively).
Patients in the group 2 received more neuromuscular blocking agents (9 vs 2 days, $p=0.01$) and corticosteroids (10 vs 6 days, $p=0.006$), and the initiation of weaning was not significantly later than group 1 (8 vs 5 days, $p=0.076$).
For diaphragmatic function, DD, DFT and TI were higher for group 1 but it did not differ significantly (2.2 cm [2–2.48] vs 1.7 cm [1.04–2.4], $p=0.23$, 35% [28–42] vs 31% [26–38], $p=0.78$ and 0.9 s [0.6–1] vs 0.6 s [0.4–0.9]; $p=0.11$, respectively).
The proportion of diaphragm dysfunction did not differ significantly between group 1 and group 2 (33% vs 40%, $p=0.67$).
**Conclusions:** Diaphragmatic excursion DFT and TI were not the most reliable predictors of weaning outcomes. However, prospective studies with a larger sample size would be necessary to evaluate the role of diaphragmatic ultrasound in ventilatory weaning.

**Topic:** Acute respiratory failure and mechanical ventilation

**Introduction:** Mechanical ventilation is a lifesaving technique that may cause damage (VILI: ventilator-induced lung injury) by submitting lung tissue to excessive mechanical stress. The specific responses of each lung cell to mechanical injury have not been dissected using single-cell technologies.
**Objectives:** To create a lung atlas of the effects of VILI by characterizing the transcriptomic responses to mechanical stretch with cell precision.
**Methods:** Nine mice were anesthetized and randomized to high-pressure mechanical ventilation (peak inspiratory pressure 25 cmH2O, PEEP 0, $n=4$) or spontaneous breathing ($n=5$) for two hours. Then, animals were sacrificed, and lung samples collected. Lung tissue nuclei were separated and labelled, and RNA of each one extracted and sequenced. RNA lectures were filtered for quality, normalized, and used to cluster lung cells using Seurat software for R and canonical markers for lung cell populations. Proportions in cell populations were compared using t tests. Differences in expression between cells and ventilatory conditions were assessed after creation pseudo-bulk transcriptomes for each cell population, using a two-factor model with the DESeq2 algorithm. The involved molecular pathways were identified using a Gene Set Enrichment Analysis (GSEA).
**Results:** Mechanical ventilation increased the proportion of specific clusters of club and alveolar type 2 cells. One thousand and fifteen molecular pathways were activated in in alveolar (type 1 and 2) and club cells. Four hundred and thirty-four pathways were enriched in the three cell types, including response to TGFb (Enrichment score 0.51, $p<10–9$) and apoptosis (Enrichment score 0.50, $p<10–5$). Pathways exclusively enriched in alveolar type 1 cells were related to immune response, including response to type II interferon (Enrichment score 0.59, $p<10–8$). Pathways specific for alveolar type 2 cells were related to DNA damage and repair (Enrichment score 0.48, $p<10–5$) and cell differentiation and epithelial to mesenchymal transition (Enrichment score 0.52, $p<10–8$). Finally, club cells showed specific enrichment of pathways related to Type I interferons (Enrichment score 0.50, $p<10–6$) and cell proliferation.
**Conclusions:** Mechanical ventilation modifies lung cell dynamics. Despite a common set of stretch-activated pathways, each distal epithelial cell type has also specific features. These results may help to identify cell-specific therapeutic targets to treat VILI.

**Introduction:** Survivors of acute respiratory distress syndrome (ARDS) may develop intensive care unit-acquired weakness (ICUAW). ICUAW prognosis ranges from complete recovery to persistent weakness. Molecular mechanisms behind these outcomes remain unclear.
**Objectives:** To investigate molecular mechanisms of ICUAW development and recovery in ARDS survivors using whole blood and skeletal muscle transcriptomics at ICU admission and during follow-up.
**Methods:** We conducted a prospective observational study. COVID19 ARDS patients who survived to their ICU stay were recruited and followed-up at 3 and 6 months after discharge. Clinical variables related to muscle performance during follow-up were included in a latent class model to classify patients in persistent weakness (PW) and strength recovery (SR) groups. Whole-blood transcriptomes (WBT) were obtained at ICU admission. Skeletal muscle samples (SKM) were collected at admission and 3 mo for single nuclei RNA sequencing (snRNA-seq). Samples with low-quality RNA and < 250 nuclei were

discarded. Differences between groups were assessed with parametric or non-parametric tests as appropriate. Differential gene expression, functional gene enrichment and skeletal muscle snRNA-seq were explored. All analysis were performed with R.
**Results:** 90 survivors completed follow-up (64 [57–73] year-old, 27.52% female). PW [$n=31$, 34%] and SR [$n=59$] groups showed no significant differences in clinical variables, apart from muscle performance. In WBT, we identified 24 differentially expressed genes between groups, related to immune response, muscle morphogenesis and transmission of nerve impulse. After quality control, 43 SKM samples were kept for snRNA-seq analysis, revealing 22 cellular populations (Fig. 1) with distinct dynamics between timepoints in PW and SR groups. PW showed a significant decrease in myonuclei 3 mo after admission, not observed in SR group, indicating potential differences in muscle recovery capacity. An increased proportion of immune cells at 3-mo versus admission was observed only in the SR group. Compared to admission, new ligand–receptor interactions emerged at 3 mo in PW group between satellite cells and FAPs, and between myonuclei, endothelial cells and pericytes. In SR, we observed new interactions at 3 mo in lymphatic endothelial with myonuclei and endothelial cells, which could suggest active tissue remodeling in the SR group. Differences in transcriptional patterns between groups and timepoints were also observed, involving pathways related to immune response, muscle differentiation and myoblast cell fate.
**Conclusions:** Transcriptomics at ICU admission may help to identify pathogenetic molecular mechanisms leading to persistent muscle weakness in ARDS survivors. PW and SR groups show different cellular dynamics that may be related to development and recovery from ICUAW.

***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001194

**Introduction:** The literature presents varied approaches to the management of tracheostomized patients, yet there is limited evidence focusing specifically on the elderly. Successful decannulation requires a comprehensive rehabilitation process that includes the assessment of airway patency, secretions, cough reflex, consciousness level, and swallowing. At our center, the rehabilitation begins with the quantification of secretions to identify patients eligible for early decannulation, thereby reducing the duration of occlusion in the selected individuals (Figure 1 and 2).
**Objectives:** To offer an epidemiological overview of the characteristics of patients undergoing tracheostomy, as well as the outcomes of implementing standardized management for successful decannulation.
**Methods:** Retrospective cohort design. Data were collected from clinical records.
**Results:** 139 clinical records out of a total of 141 tracheostomies in adults (71% male, 29% female) were reviewed. The average patient age was 60 years, 50% elderly. 91% of these patients were admitted to the Intensive Care Unit (ICU), with prolonged ventilation (45%) and neurological compromise (28%) being the primary reasons for tracheostomy. 9% of patients were from general wards, with indications related to extrinsic airway compression or subglottic stenosis. In 96% of cases, the cannula size was 8 or larger. In the ICU, the average pretracheostomy ventilation period was 20 days, and the average time until weaning off ventilation post-tracheostomy was 18 days. Out of the 141 tracheostomies performed, 22 did not proceed to decannulation. The rehabilitation process averaged 25 days, with partial occlusion in 70% of cases and complete occlusion in 30%; the average time to occlusion before decannulation was 10 h. The decannulation success rate was 98%.
**Conclusions:** Given that the study focused on a geriatric population, which inherently has less functional reserve, the high success rate underscores the effectiveness of our hospital's management approach, indicating that it does not increase risks.

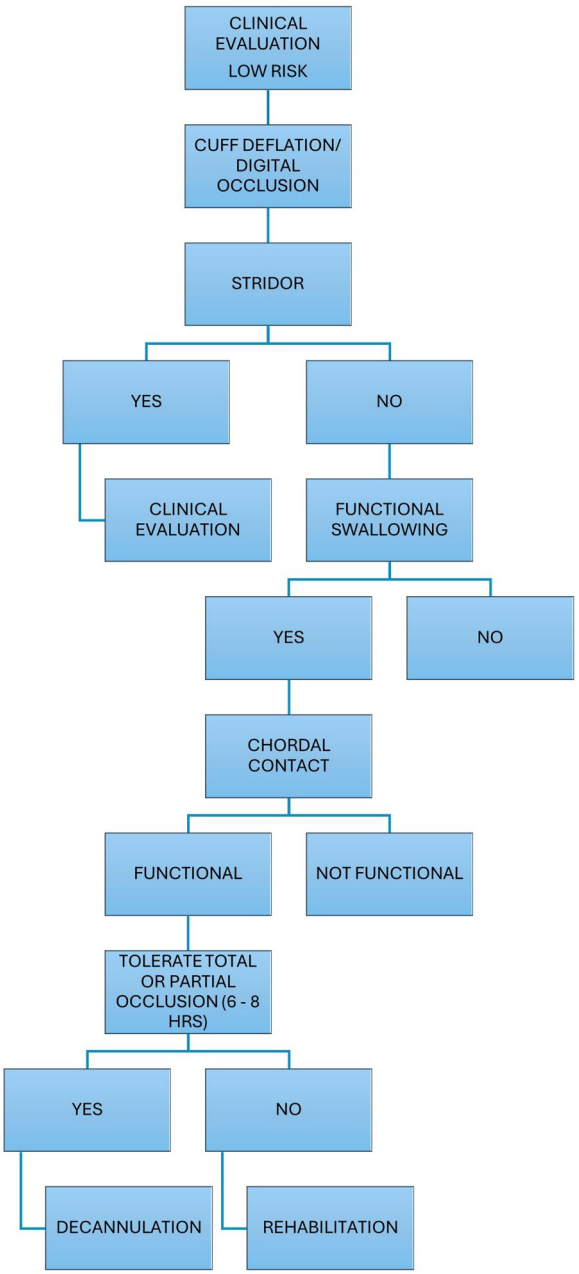

**Fig. 1 (abstract 001194)** Low-risk management due to minimal respiratory secretions

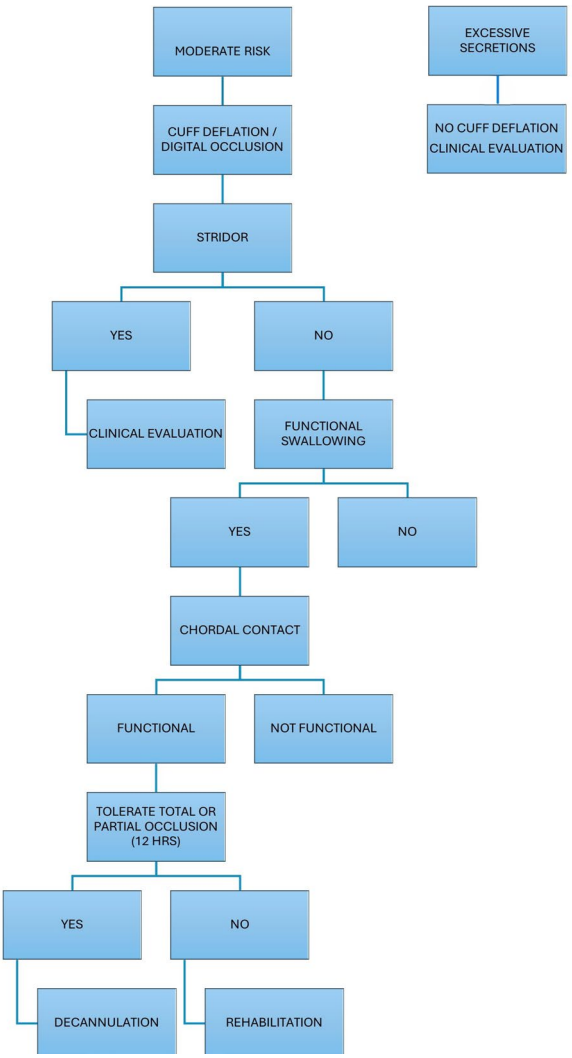

**Fig. 2 (abstract 001194)** Managing moderate to high-risk based on secretion volume

### Predictive value of neutrophil-to-lymphocyte ratio (NLR) to predict the new onset of atrial fibrillation (NOAF) in patients with septic shock

S. Humbre[1], L. Shah[2], A. Lokhande[3], P. D'costa[4], V. Lobo[5]
[1]ICCU, KEM Hospital, Pune, India; [2]ICCU and Neurocritical Care, KEM Hospital, Pune, India; [3]ICU-3, KEM Hospital, Pune, India; [4]ICU, KEM Hospital, Pune, India; [5]Nephrology ICU, KEM Hospital, Pune, India
**Correspondence:** S. Humbre
***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001195

**Introduction:** Atrial fibrillation is the commonest arrhythmia in septic shock. In septic shock, there is myocardial dysfunction due to contracting and relaxing abnormality. In addition to this, electromechanical abnormality also exists. An exact cause of this is not known, although inflammation is the proposed cause by many.
Neutrophil to lymphocyte ratio (NLR) is emerging as a new, cost effective marker in various illnesses including inflammation and sepsis.
**Objectives:** Since the proposed mechanism of new onset of atrial fibrillation (NOAF) is inflammation, we conducted a prospective observational study to evaluate the predictive value of NLR to predict NOAF in septic shock.
**Methods:** 97 patients, who were admitted with septic shock or developed septic shock during their ICU stay, were included in the study assuming NOAF developing in 40% of all cases and a drop out rate of 10%. A written informed consent was obtained from relations. NLR values were obtained from the hemogram on day 1, 3 and 5 of septic shock.
Our exclusion criteria were age < 18 years, pregnancy, neutropenia (ANC < 1500), patients with pre-existing valvular heart disease, immunocompromised status due to radiotherapy, steroids (long term), stem cell transplant and shock due to other causes.
Continuous ECG monitoring was done to detect new onset of atrial fibrillation (NOAF). Patients with NLR value > / = 3.53 were considered as having test positive.
Sensitivity, specificity, positive predictive value and negative predictive value were calculated using SPSS software from true positive, false positive, true negative and false negative test. Using different NLR thresholds, receiver operating characteristic (ROC) curve was constructed.
**Results:** We found that, in our study, 47 patients out of 97 (48.5%) had NOAF. Most of the patients with NOAF were in the age group 31–40 years (31.9%). Mean NLR was high on day 1 (20.04 ± 11.9) compared with day 3 (19.7 ± 11.5) and day 5 (16.6 ± 9.9) in patients who had NOAF. Considering the cutoff value for NLR as 3.53, sensitivity of NLR to predict NOAF was high on day 3 (95.6%) compared with day 5 and day 1. The specificity was on highest on day 1 (20%) compared with day 3 and day 5. Positive predictive value (PPV) was highest on day 1 (51.8%) and negative predictive value (NPV) was highest on day 3 (77.8%).
Receiver operating characteristic (ROC) curve analysis showed that area under curve (AUC) on day 1 was 0.61, on day 3 was 0.61 and on day 5 was 0.57.

**Table 1 (abstract 001195)** Sensitivity and specificity of NLR in patients with NOAF

| | Day 1 | Day 3 | Day 5 |
|---|---|---|---|
| Sensitivity | 91.5% | 95.6% | 90.2% |
| Specificity | 20% | 14.6% | 17.7% |
| Positive predictive value(PPV) | 51.8% | 51.7% | 50% |
| Negative predictive value (NPV) | 71.4% | 77.8% | 66.6% |

**Table 2 (abstract 001195)** ROC curve analysis

| Day | AUC | Standard error | p value | 95% CI |
|---|---|---|---|---|
| Day 1 | 0.611 | 0.064 | 0.088 | 0.486–0.735 |
| Day 3 | 0.610 | 0.064 | 0.089 | 0.486–0.735 |
| Day 5 | 0.575 | 0.065 | 0.250 | 0.448–0.702 |

**Conclusions:** Neutrophil-to-lymphocyte ratio (NLR) with a cutoff value of 3.53 has good sensitivity on day 3 to predict the NOAF in patients with septic shock. In addition, AUC had a good value on day 3. Further trials with larger sample size are required to prove its effectiveness in predicting NOAF in septic shock.

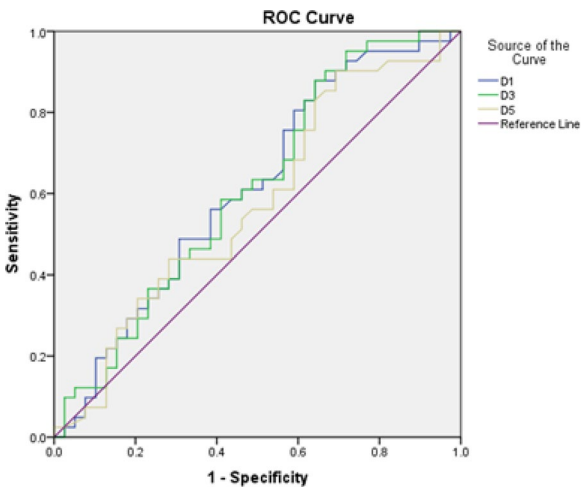

**Figure ! (abstract 001195)** Receiver operating characteristics (ROC) analysis for NLR in patients with NOAF in septic shock on days 1, 3 and 5

**Introduction:** Acute kidney injury (AKI) is a deterioration of kidney function that can develop in hours, days or weeks and affects 30% of patients admitted to the Intensive Care Unit (ICU), contributing to morbidity and mortality. Mortality can reach 50–80% despite the use of dialysis technique, especially if associated with multiple organ failure (MOF). In patients undergoing emergency surgery, AKI is a common postoperative complication. The identification of high-risk patients may facilitate the implementation of important procedures to prevent and treat AKI in patients undergoing surgery.
**Objectives:** The objective of this study was to find predictors of AKI following ICU admission in urgent surgical patients and to verify whether there is a relationship between AKI development and the prognosis of the patient.
**Methods:** This is a retrospective single-center study evaluating surgical patients admitted to a Portuguese ICU in 2023. Patient variables were divided in demographic (age, sex), past medical history, emergency department (ED) related (vitals, creatinine, C-reactive protein (CRP), lactate, and pH), surgical procedure related (time from admission, duration of surgery, use of vasopressors, and fluid balance) and ICU related (SOFA, vitals, diuresis at 6 and 24 h). Primary endpoint was defined as development of acute kidney injury and secondary endpoints as death and need for renal replacement therapy (RRT).
**Results:** A total of 95 patients was selected, 44.2% female with a mean age at admission of 62.8 ± 28.2 years. AKI occurred in 55.8% of these patients with 8% requiring RRT. Development of AKI during UCI stay was associated with past medical history of heart failure ($\varphi = 0.26$, $p = 0.02$), mean arterial pressure under 65 mmHg at ED admission ($\varphi = 0.34$, $p < 0.01$), and need for vasopressors during surgical procedure ($\varphi = 0.34$, $p < 0.01$). Patients who developed AKI were older (73.9 vs. 48.7 years, $p < 0.01$) showed higher values of lactate (4.55 vs. 2.37, $p = 0.02$), creatinine (4.38 vs. 2.22 mg/dL, $p < 0.01$), CRP (15.5 vs. 8.96 mg/dL, $p = 0.03$) and lower pH (7.10 vs. 7.40, $p = 0.04$), and mean arterial pressure (MAP) (75.6 vs. 86.9 mmHg, $p < 0.01$) at admission. Mean fluid balance during procedure was positive in the AKI group, without achieving statistical significance (+435 vs −0.06 L, $p = 0.08$). There was an association between development of AKI and inpatient mortality ($\varphi = 0.36$, $p < 0.01$). Moreover, patients evolving to death showed a higher mean value of creatinine (2.9 vs. 1.9 mg/dL).
**Conclusions:** This study underlines the association between AKI and mortality and helps prevent and early diagnose AKI in patients undergoing surgery.
According to the results obtained in this study, the probability of developing AKI is higher in older patients, with higher lactate and CRP values and/or lower pH and MAP values. Although the results obtained are in agreement with the results obtained in the few studies carried out in this area, the present study still reveals some limitations.

**Introduction:** Sepsis is a life-threatening and heterogeneous clinical syndrome characterized by concomitant inflammatory and immunosuppressive mechanisms. (1,2) The latter is associated with occurrence of nosocomial infections, viral reactivation, and poor outcomes. Administering biomarker-guided immunotherapy to patients at the appropriate immunological phase has the potential to be a significant breakthrough in sepsis treatment. (3) Decreased human leukocyte antigen (HLA)-DR expression on antigen-presenting cells, including monocytes, is advocated as a hallmark of sepsis-induced immunosuppression. (4) Knowledge on the relationship between surface HLA-DR expression and cytokine production capacities of monocytes purified from sepsis patients remains limited.
**Objectives:** Here, we sought to evaluate the association of monocyte surface HLA-DR expression to ex vivo cytokine production capacities.
**Methods:** This study was part of the Molecular Endotype-Specific Dynamics of Lung Endothelial Barrier Integrity in Sepsis (MENDSEP) project, a prospective single-centre study in the mixed ICU of a teaching hospital in Malta (Mater Dei hospital; NCT01905033). Sepsis ($n = 14$) was defined as the presentation of community- or hospital-acquired pneumonia diagnosed on ICU admission based on evident new or progressive infiltrate, consolidation, cavitation, or pleural effusion on the chest X ray or CT scan. Age- and sex-matched control participants ($n = 16$) were recruited from a long-term care facility in Malta (Saint Vincent de Paul hospital). All patients and control participants provided informed consent. Monocytes were purified from heparinised blood. Flow cytometry was utilized to profile CD14 and HLA-DR surface expression. Monocytes were exposed to 10 ng/mL *E. coli* lipopolysaccharide (LPS) for 24 h, and IL-1β was quantified in supernatants by ELISA. Data were analysed using Wilcoxon rank sum or Spearman's correlation tests. $P < 0.05$ demarcated significance.
**Results:** The monocytes of patients with sepsis showed a significant decrease in the levels of surface CD14 + HLA-DR + (double positive) compared to the control participants. Following a 24-h exposure to LPS, monocytes from sepsis patients exhibited a significant decrease in the production of IL-1β compared to the control group. Correlation tests revealed a direct relationship between percent CD14 + HLA-DR + and IL-1β production for either sepsis patients (rho = 0.5) or control subjects (rho = 0.42).
**Conclusions:** Septic monocytes are characterized by decreased levels of surface HLA-DR, and reduced production of IL-1β in response to LPS, which are in line with several reports. Production of IL-1β was directly related to the extent of HLA-DR expression on monocytes. Our

findings lend weight to the utility of monocyte HLA-DR in identifying sepsis-induced immunosuppression.

## Vasoactive Ventilation Renal Score as a predictor of mortality in septic shock in the Intensive Care Unit

S. I. Alba Cuevas[1], J. Garduño-López[1], M. A. Amezcua-Gutiérrez[1], J. C. Gasca-Aldama[1], M. A. Carrasco Flores[1], N. M. Sánchez Parada[1], J. E. Castrejón Sánchez[1], N. L. ***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001198

**Introduction:** Septic shock represents a frequent entity in the Intensive Care Unit (ICU), with an estimated incidence in different cohorts of 35.3% and an overall mortality of 63.4% (1). The Vasoactive Ventilation Renal Score (VVR), which has been widely applied to evaluate outcomes in post-cardiac surgery patients (2), may represent a valid index to predict outcomes in the evaluation of septic shock because it integrates the cumulative dose of vasopressor or inotropic agent, creatinine delta and ventilatory dynamics (3), which reflect the severity of the disease. It should be noted that a specific association has not been established in critically ill patients with septic shock (4), so it could be a tool that could allow the estimation of mortality risk in this group of patients.

**Objectives:** To evaluate if the Vasoactive Ventilation Renal Score is useful in predicting mortality in patients with septic shock in the Intensive Care Unit.

**Methods:** This is a prospective, longitudinal, analytic clinical assay. We included patients with septic shock admitted to the ICU. We calculate the VVR Score at admission to the ICU and 24 h later. The VVR was calculated as follows: Vasoactive Inotropic Index (VIS)+Ventilation Index (VI)+Renal Score (change in serum creatinine (Cr) from admission × 10). VIS was calculated using the following equation: Dopamine dose (µg/kg/min)+Dobutamine dose (µg/kg/min)+100 × Epinephrine dose (µg/kg/min)+10 × Milrinone dose (µg/kg/min)+10,000 × Vasopressin dose (µg/kg/min)+100 × Norepinephrine dose (µg/kg/min) (5). VI was calculated using the following formula: VI=(respiratory rate x (Maximum pressure − PEEP) x PaCO2)/1000, when the patient was not ventilated, the score was 0. Δ creatinine was calculated by subtracting the serum creatinine (in mg/dL) at 24 h of admission from the serum creatinine at the admission to the ICU. The VVR was calculated using the following formula: VVR=VIS+VI+(ΔCr × 10) (6). We measured APACHE II, SOFA and SAPS II.

**Results:** We evaluate a total of 30 patients, 43.3% ($n=13$) were males and 56.7% ($n=17$) were females, of which 83.3% ($n=25$) survived and 16.6% ($n=5$) died. The etiology of the septic shock was mostly abdominal (50%). The median of VVR calculated at the time of admission was 30.9 and 67.8 (survivors and non-survivors), and at 24 h were 21.35 and 88.5 (survivors and non-survivors) both measurements with statistical significance ($p=0.021$ survivors and $p=0.047$ in non-survivors). By applying Youden test, we calculate a value of VVR of 41.7 at admission and 47.9 24 h later, with the area under the curve for VVR at the time of admission was 0.95 ($p=0.001$) and at 24 h of 1.0 ($p=0.001$).

**Table 1 (abstract 001198)** Median scores and standard deviation at the time of ICU admission for all patients; comparison of all variables between ICU survivors and ICU non-survivors

| Variable | Total | ICU survivors—median (SD) | ICU non-survivors—median (SD) | *p* |
|---|---|---|---|---|
| APACHE II | 22.10 ± 9.74 | 21.4 (0.90) | 25.6 (1.80) | 0.738 |
| SOFA | 12.33 ± 5.28 | 11.68 (1.84) | 15.60 (2.70) | 0.004 |
| SAPS II | 38.47 ± 18.78 | 36.04 (1.14) | 50.06 (0.144) | 0.233 |

**Table 2 (abstract 001198)** Median of VIS, VI, Creatinine and VVR measurements at the time of admission and 24 h later and its relationship with mortality

| Variable | Admission ICU survivors Median (SD) | 24 h ICU survivors Median (SD) | *p* | Admission ICU non-survivors Median (SD) | 24 h ICU non-survivors Median (SD) | *p* |
|---|---|---|---|---|---|---|
| VIS | 15.17 (1.77) | 9.92 (1.74) | 0.033 | 52.40 (1.17) | 65.60 (2.07) | 0.000 |
| VI | 12.88 (2.19) | 8.52 (1.19) | 0.050 | 18.62 (1.65) | 26.10 (3.9) | 0.000 |
| Creatinine | 1.93 (1.18) | 1.64 (1.16) | 0.001 | 3.90 (0.55) | 4.22 (0.67) | 0.000 |
| VVR | 30.9 (1.25) | 21.35 (0.13) | 0.021 | 67.8 (1.25) | 88.5 (4.37) | 0.047 |

**Conclusions:** Since there is lack of evidence of the utility of this index in adult patients in the context of septic shock, we conclude with this clinical assay that the VVR Score is an useful tool, with high specificity and sensibility, to predict mortality in patients with septic shock admitted to the ICU when measured at the time of admission and 24 h later.

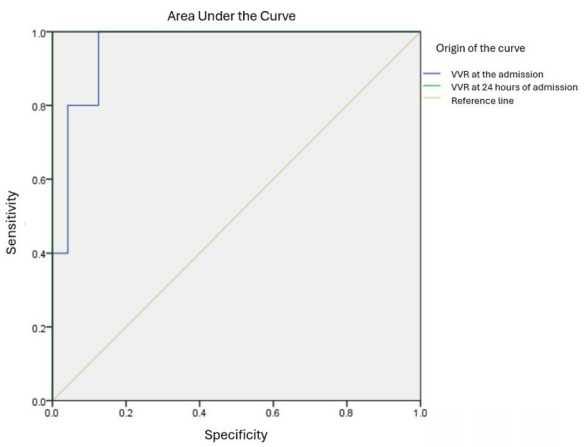

**Fig. 1 (abstract 001198)** Area under the receiver-operating characteristic curves expressing the VVR at the time of admission and 24 h later

### Characteristics and outcomes of super elderly patients with community-acquired pneumonia: a multicenter study of 10,763 patients in Brazilian ICUs

G. Martins[1], G. Moralez[1], L. Bastos[2], J. Pareto[2], I. Faria[1], J. Salluh[3]
[1]Intensive Care, IDOR - Instituto D'Or de Pesquisa e Ensino, Rio de Janeiro, Brazil; [2]Department of Industrial Engineering (dei), Pontifical Catholic University of Rio de Janeiro, Rio de Janeiro, Brazil; [3]Institute for Research and Education, D'Or, Rio de Janeiro, Brazil
**Correspondence:** G. Martins
***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001199

**Introduction:** Community-acquired pneumonia (CAP) is a major cause of Intensive Care Unit (ICU) admission for elderly patients worldwide. The biological and functional heterogeneity of very old patients presents a major challenge for prognostication and patient management in ICUs. A knowledge gap exists in the evidence supporting triage and care planning for elderly patients.
**Objectives:** The goal of this study was to describe clinical characteristics and outcomes and identify phenotypes associated with in-hospital mortality.
**Methods:** We prospectively included consecutive patients from 147 ICUs (60 Hospitals). Anonymized data were collected (2019 and 2022 and 2023, January to July). The study was approved by the IRB (CAAE: 17079119.7.0000.5249). Super-elderly were defined as 80 years old and more. The outcome of interest was hospital mortality. We described the super-elderly patients according to clinical characteristics, resource use, and hospital outcomes. Descriptive statistics were used for all variables. Parametric tests were used to determine group differences. For subgroups identification, we used a modified K-means clustering algorithm. We assessed the phenotypes characteristics and their ability to discriminate between outcomes.
**Results:** From 307,554 patients, 18,017 had more than 65 years old and had CAP as the admission diagnosis. The super-elderly group had 10,763 patients presenting a median SAPS score of 57 (IQR 54;62) and 2605 (24%) were frail. Performance status before admission was "independent" 2821 (35.6%), "partially dependent" 4483 (41.65%) and 2448 was "bedridden" (22.75%). Median ICU length of stay (LOS) was 5 (IQR 3;9) days. Median hospital LOS was 10 (IQR 7;17) days. ICU and hospital mortality were, respectively, 10.31% and 17.94%. Of the super-elderly patients, 1151 (10.31%) were mechanically ventilated, 405 (3.76%) received renal replacement therapy, 1324 (12.3%) received vasopressors. For mechanically ventilated (MV) patients, the hospital mortality was 67.76% (780 patients). Higher SOFA score, frailty, and poor functionality were associated with higher mortality for super elderly in the univariate analysis (Fig. 1). Preliminary cluster analysis showed two groups. Cluster "2" was associated to a higher hospital mortality (22%), have distinct characteristics: higher median age, higher frequency of Neurologic disfunction at admission, poor functional status and dementia (Table 1). The resource use was different for RRT and tracheostomy. There was no difference for SAPS 3 score, frequency of MV at admission, vasopressor use, ICU and Hospital LOS between the groups.
**Conclusions:** This multicenter study identified significant heterogeneity among super-elderly patients with CAP admitted to ICUs. By applying a modified K-means clustering algorithm, we found two distinct patient phenotypes. The cluster characterized by older age, more frequent neurological dysfunction at admission, dementia, and poor functional status had worse hospital outcomes. These findings can be useful as prediction tools, paving the way to more informed and rational ICU resource allocation for this vulnerable group.

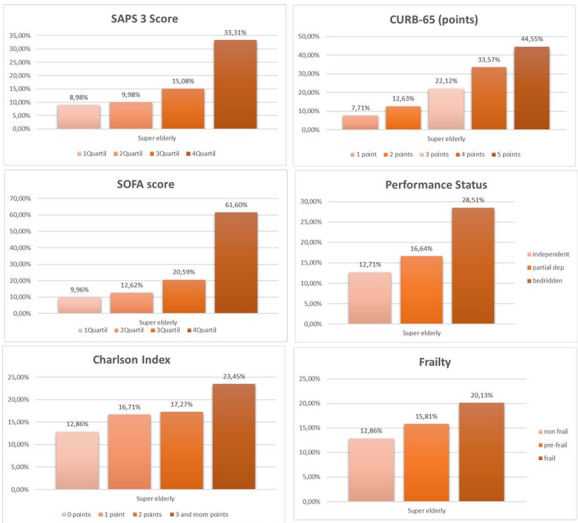

**Fig. 1 (abstract 001199)** Clinical characteristics and outcomes

**Table 1 (abstract 001199)** Cluster analysis. Variables that showed significant differences between groups

| | | Cluster 1 | Cluster 2 |
|---|---|---|---|
| | age (median, IQR) | 84 (82;86) | 91 (89;94) |
| Acute disfunction at admission | Neurologic | 29% | 40% |
| Geriatric assessment | Dementia | 26% | 37% |
| Performance status | Bedridden | 18% | 28% |
| Vital suport | Renal Replacement Therapy | 4.6% | 2.9% |
| ICU Interventions | Tracheostomy | 2.4% | 1.2% |
| Outcome | Hospitalar death | 14% | 22% |

***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001200

**Introduction:** Vasopressin is currently suggested as a second-line vasopressor in patients with septic shock on norepinephrine and persistent arterial hypotension instead of increasing norepinephrine dose (1). Nevertheless, the place of vasopressin and its analogues in patients with septic shock is still debated with significant heterogeneity between intensive care units (ICU).
**Objectives:** The aim of this survey was to obtain an up-to-date picture of the use of vasopressin and terlipressin in patients with septic shock.
**Methods:** This is an international survey endorsed by the European Society of Intensive Care Medicine disseminated worldwide. All items were selected according to the different areas of uncertainty and research identified from current international recommendations. One response per intensivist was expected.
**Results:** Overall, 461 intensivists from 72 different countries responded to the survey: 303 (66%) worked in Europe, 158 (34%) worked in non-European countries and 226 (49%) worked in a teaching hospital. Vasopressin or analogues were available in 91% of cases. The reported indications for vasopressin or terlipressin were refractory septic shock (66% of cases), catecholamine sparing in all types of refractory shock (56% of cases), refractory vasoplegic shock (other than septic) without reduced systolic function (52% of cases) and septic shock with high cardiac output and low systemic vascular resistance (49% of cases). The main reported contra-indication for vasopressin or terlipressin was non-occlusive mesenteric ischemia (39% and 32% of cases, respectively). Overall, 342 (74%) intensivists used vasopressin or terlipressin, mainly as a second-line vasopressor after initial resuscitation with fluids and norepinephrine (93% of cases). The main trigger for vasopressin or terlipressin use was low mean arterial pressure (MAP) (90% of cases) and the main goals were to increase blood pressure and decrease the catecholamine load. When the duration of administration was not considered, a norepinephrine base dose between 0.25 and 0.50 µg/kg/min was the most frequent trigger for vasopressin or terlipressin administration (52% of cases). When the duration of administration was considered, a norepinephrine base dose > 0.25 or > 0.50 µg/kg/min for > 2-6 h was the most frequent trigger (59% of cases). The most frequent initial doses of vasopressin were 0.01 or 0.03 UI/min (27% of cases for both doses) and were mainly titrated thereafter to target MAP. The main triggers for tapering vasopressin or terlipressin were MAP level (84% of cases) and first-line vasopressor dose (59% of case). Vasopressin or terlipressin were tapered after the dose of the first-line vasopressor was lowered below a predefined threshold in 40% of cases with a progressive decrease in doses in 84% of cases.
**Conclusions:** There is still a significant heterogeneity in the use of vasopressin in patients with septic shock. The survey is still ongoing.

**Introduction:** The physical environment of the ICU is an under-appreciated reservoir of resistant organisms growing on surfaces as biofilms. As such, the ICU acts as an incubator for resistant pathogens and plays a role in antimicrobial resistance (AMR). AMR is a problem in Africa, where a lack of surveillance data hinders intervention activities.
**Objectives:** The objective is to evaluate whether the AMR patterns in clinical isolates are similar to those of viable microbes in the ICU-built environment.
**Methods:** A prospective study was conducted in 2 ICUs at a public and private hospital in Cape Town. Patient culture results, taken as part of patient treatment from 1 February to 31 March 2022, were included. Microbiological samples were collected from various "high-frequency" touch surfaces, water sources, faucet outlets and wastewater drains in the ICUs on two occasions during the study period.
**Results:** ICU A admitted 328 cardiothoracic and vascular surgery patients, the mean (SD) age was 65 (14) years, 119 patient specimens, 63 surface swabs and 14 water specimens (sampling 1) and 66 surface swabs and 17 water specimens were collected. ICU B admitted 128 trauma and surgical patients; the mean (SD) age was 44 (16), 374 patient specimens, 47 surface swabs and 10 water specimens (sampling 1) and 48 surface swabs and 9 water specimens were collected. Summary of main results in table.

| | Organism | Clinical source | Environmental source |
|---|---|---|---|
| ICU A | Non-MDR *Serratia marcescens,* AST near identical | Sputum × 2 | Hand wash sink drain, patient bedside drawer, IV pump |
| | MR *S Staphylococcus epidermidis*, AST not identical | Blood × 1 | Nursing station vital stats monitor mouse |
| | MDR *Klebsiella pneumonia,* AST near identical | Blood × 6 | Bed sink drain |
| | *Pseudomonas aeruginosa* AST identical | Urine × 1 | Staff bathroom drain, sluice drains |
| ICU B | MDR A*cinetobacter baumannii* and *Acinetobacter* spp. AST identical | Tracheal aspirate × 5, peritoneal aspirate × 1, pleural aspirate × 1, bronchial aspirate × 1, blood × 2, urine × 2, catheter tip × 3 | Patient bedside drawer, admission book, telephone handset, medication prep surface, bedpan wash sink and drains |

| | Organism | Clinical source | Environmental source |
|---|---|---|---|
| | MDR *Acinetobacter baumannii* AST identical Sensitive to Gentamycin | Tracheal aspirate × 1, urine × 2, catheter tip × 1, wound swab × 1 | Bedpan wash sink, sluice room drain |
| | Non-MDR *Serratia marcescens* AST identical | Tracheal aspirates × 3 | Telephone handset, patient bedside drawer, hand wash sink |
| | MDR *Klebsiella pneumonia* AST near-identical | Sputum × 1 | Patient bedside drawer |

**Conclusions:** The AMR profiles of clinical isolates implicated in hospital-acquired infections matched those of environmental isolates in some, but not all, instances. This indicated that other reservoirs of AMR organisms might be present in the environment, such as colonised but asymptomatic patients or healthcare workers.

### Prediction of the volume response through the increase in the time velocity integral after a change in the positive pressure at the end of expiration (PEEP Study Test)

N. M. Sánchez Parada[1], J. Garduño-López[1], M. A. Amezcua-Gutiérrez[1], J. C. Gasca-Aldama[1], S. I. Alba Cuevas[1], E. Hernandez-Dominguez[2], J. E. Castrejón Sánchez[3], C. E. Lopez-Rodriguez[2], N. L. Novoa Santander[3], M. A. Carrasco Flores[1], M. A. Juan Gomez[1], F. Ordóñez Hernández[4], G. D. Hernández-López[1], K. H. Lopez Rodriguez[5], M. Vidals-Sánchez[5], A. M. ***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001203

**Introduction:** Determining the patient's ability to respond to volume expansion is essential during the management of hemodynamically unstable patients in the Intensive Care Unit (ICU), trying to avoid fluid overload that causes an increase in mortality. The increase in positive end-expiratory pressure (PEEP) decreases stroke volume (SV) and is explained by the decrease in venous return as a result of an increase in pleural pressure and with this could induce a response to fluids.
**Objectives:** To evaluate whether the increase in time velocity integral (TVI) following a change in positive end-expiratory pressure (PEEP) predicts the volume response.
**Methods:** This is a prospective, longitudinal, comparative, analytical study. Patients who were admitted to the ICU with mechanical ventilation were included. The volume responsiveness was measured by measuring the baseline ITV and after passive leg raising (PLR), presenting an increase of 10%. The PEEP test consisted of increasing the PEEP level to the baseline level by 5 cmH2O for one minute, obtaining an ITV measurement, subsequently decreasing it back to the baseline PEEP with its respective ITV measurement. During the test, the patient had continuous monitoring.
**Results:** A total of 54 patients were registered with 70.4% ($n=38$) women and 29.6% men ($n=38$) (Table 1). It was demonstrated that there is a significant statistical difference ($p=0.001$) after performing PLR and 55.6% ($n=30$) were defined as responders and 44.4% ($n=24$) as non-responders with an average ITV of 21.68 ± 3.5 ($p=003$) and 19 ± 2.5 ($p=0.002$), respectively. After decreasing the PEEP delta to 5 cmH2O, the average ITV for responders was 21.6 ± 3.6 ($p=0.000$) and for non-responders 18.4 ± 2.5 ($p=0.000$) (Figure 1). The average PEEP at the beginning of the study was 6 cmH2O with no difference observed between responders and non-responders ($p=0.369$). The area under the curve of the PEEP test for detecting volume responsiveness was 0.801 (95% CI: 0.85 to 0.91) ($p=0.001$) (Figure 2).

| Variable | Total population ($n=54$ | Responder ($n=30$) | Non-responder ($n=24$) |
|---|---|---|---|
| Gravity scales | | | |
| APACHE | 17.35 ± 6.7 | 18 ± 7.4 | 15.74 ± 5.6 |
| SOFA | 9.5 ± 3.28 | 9.46 ± 3.2 | 9.65 ± 3.44 |
| Time velocity integral (TVI) | | | |
| TVI baseline | 19.0 ± 2.9 | 18.7 ± 3.2 | 19.3 ± 2.7 |
| TVI after PLR | 20.4 ± 3.3 | 21. 68 ± 3.5 | 19 ± 2.5 |
| TVI Δ 5 cmH2O | 17.3 ± 3.2 | 17.1 ± 3.5 | 17.7 ± 2.7 |
| TVI baseline 2 | 20.5 ± 3.6 | 22 ± 3.6 | 18.54 ± 2.5 |
| Causes of shock (%) | | | |
| Hypovolemic | 9 (16.7%) | 9 (16.7%) | 0% |
| Abdominal | 14 (25.9%) | 9 (16.7%) | 9.3% (5) |
| Soft tissue | 4 (7.4%) | 2 (3.7%) | 2 (3.7%) |
| Pulmonary | 25 (46.3%) | 10 (18.5%) | 15 (27.8%) |
| Pulmonary and abdominal | 2 (3.7%) | 0% | 2 (3.7%) |

**Conclusions:** The response to volume can be detected using changes in mechanical ventilation; both the tidal volume change and the PEEP test using the left ventricular outflow tract velocity time integral (LVOT VTI) as a surrogate for stroke volume.

## A scoping review of approaches to alarm fatigue reduction in intensive care and telemetry units

M. Nemeckova[1], L. Tinkler[2], I. Joy[3]
[1]Critical Care, Royal Victoria Infirmary, Newcastle Upon Tyne, United Kingdom; [2]Trust lead for Nursing, Midwifery and Allied Health Professionals (NMAHP) Research, Newcastle Freeman Hospital, Newcastle Upon Tyne, United Kingdom; [3]Executive Director of Nursing, Newcastle Freeman Hospital, Newcastle upon Tyne, United Kingdom
**Correspondence:** M. Nemeckova
***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001204

**Introduction:** Alarm fatigue is a widely recognised patient safety risk that occurs when health professionals are exposed to excessive alarms, causing sensory overload and desensitising nurses' responsiveness to critical alarms (Schmid et al., 2011). Those affected by alarm fatigue may postpone or dismiss critical alarms (Sendelbach & Funk, 2013), leading to unintended consequences for both patients and care providers. There is a general agreement that implementing alarm management strategies can contribute to reducing alarm fatigue (Paine et al. 2015), yet the description of what sort of strategies can reduce alarm fatigue and how these strategies contribute to alleviating alarm fatigue in hospital settings remains unclear.
**Objectives:** This review aims to 1) synthesise the strategies employed to reduce alarm fatigue, including excessive false and non-actionable alarms which are major factors causing alarm fatigue among nurses, and 2) understand how these strategies contribute to alleviating alarm fatigue in ICU and telemetry settings.
**Methods:** This scoping review was conducted according to the Guidance for conducting systematic scoping reviews (Peters et al. 2015). The PubMed, CINAHL and ProQuest databases were searched for manuscripts published between 2013 and 2023. The search strategy followed the most recent Preferred Reporting Items for Systematic Reviews and Meta-Analyses for Scoping Reviews (PRISMA-ScR) guidelines (Tricco et al. 2018).
**Results:** This review included twenty-seven articles focused on alarm management strategies for the reduction of alarm fatigue in healthcare settings. We found a lack of studies that sought to decrease alarm fatigue directly; instead, the predominant focus was on reducing alarm quantity, with the anticipated effect of reducing alarm fatigue. Alarm management strategies include reducing unnecessary telemetry use, reducing invalid alarms, reducing valid but nonactionable alarms, enhancing the signals of actionable alarms for improved responsiveness and implementing a care bundle. These interventions addressed various types of problems potentially contributing to alarm fatigue. These interventions were implemented by various members of the healthcare team. Studies aimed at bundled interventions were associated with greater alarm fatigue reduction benefits in healthcare settings than those targeting a single intervention alone.
**Conclusions:** Although efforts have been made to reduce alarm fatigue, no single approach has been found universally beneficial, acknowledging diverse types of alarms contributing to alarm fatigue. These interventions were implemented by various members of the healthcare team, underscoring the multifaceted and collaborative nature of the strategies employed. The recognition of the multifaceted nature of problematic alarms suggests that a series of different interventions, rather than a singular approach, that together form a framework have a greater potential for alarm fatigue reduction in healthcare settings.

### The climate impact of an intensive care unit in Sweden, a life cycle assessment

L. Hemberg[1], P. Bentzer[1]
[1]Anesthesiology and Intensive Care, Department of Clinical Sciences Lund, Lund University, Lund, Sweden
**Correspondence:** L. Hemberg
***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001205

**Introduction:** Climate change is already impacting human health and is perceived as one of the greatest health issues for the twenty-first century. The health sector's climate footprint is equivalent to 4.4% of the global net emissions of greenhouse gases (HCWH, Arup, 2019). Intensive care is a particularly resource demanding sector of health care but little is known about its climate footprint (Bein T, Koch S, Schulz C. 2021).
**Objectives:** The objective of this study was to estimate the total climate impact of a Swedish ICU and to identify modifiable hotspots.
**Methods:** A process-based life cycle assessment was conducted to estimate the climate impact per bed-day at the Helsingborg hospital ICU in southern Sweden using ReCiPe 2016 method. The analysis included single-use items, reusable items and textiles, pharmaceuticals, fluids, medical air and oxygen, and energy consumption for electronic equipment, lighting, and heat-ventilation-air condition (HVAC). Results are reported as median and 95% reference intervals [2.5th–97.5th percentiles] emissions of carbon dioxide equivalents (CO2eq).
**Results:** The climate impact of one bed-day at the ICU was 32 kg CO2eq [30–35]. About 60% of the total impact came from the production and waste management of single-use items, followed by the unit's energy consumption representing 25% of the total impact (Fig. 1, panel A). Of the single-use items, aprons, gloves and woven gauzes were the top three contributors and contributed by 14%, 12% and 11% of the total climate impact from single-use items (Fig, panel B). The sensitivity analysis showed that changing from a Swedish, mainly renewable energy mix, to an average European or a fossil intensive energy mix increased the climate impact to 77 kg CO2eq [73–83] and 150 kg CO2eq [116–197], respectively.
**Conclusions:** The opportunity to reduce the climate impact from Swedish intensive care mainly lies in the reduced use of single-use items. However, for countries which are dependent on fossil intensive energy sources, the main opportunity to reduce intensive care's climate impact is through the transition to green energy.

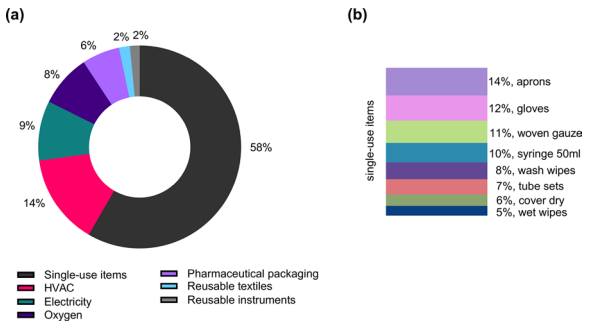

**Fig. 1 (abstract 001205)** (A) Contribution analysis showing the climate impact from different activities at the ICU. HVAC = heat, ventilation, and air conditioning. (B) Contribution analysis showing the single-use items which contributes by ≥ 5% of the single-use items total climate impact

***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001206

**Introduction:** Early and precise prognosis determination in cardiac arrest survivors remains challenging despite multimodal approach. Currently, the only guidelines-recommended biomarker for early prognostication is neuron-specific enolase (NSE).
**Objectives:** The aim of our study was to compare prognostic values of Galectin-3 (Gal) with NSE at different timepoints after cardiac arrest and with combination of both biomarkers.
**Methods:** Eligible subjects for this prospective study were out-of-hospital cardiac arrest survivors. All patients were treated with targeted temperature management (33 °C for 24 h) using an endovascular device. Blood samples for the measurements of NSE and Gal levels were drawn at 24 h (D1), 48 h (D2), 72 h (D3), and 96 h (D4) after hospital admission. Thirty-day neurological outcomes according to the Modified Rankin Scale (mRS) were evaluated as clinical endpoints, and poor outcome was defined as mRS 4–6. Prognostic values of NSE and Gal for the prediction of poor outcomes were determined using ROC analysis.
**Results:** A total of 83 cardiac arrest survivors (mean age 65 years) were enrolled in the present study. The area under the ROC curve (AUC) for NSE was 0.779, $P < 0.001$ at D1, 0.936, $P < 0.001$ at D2, 0.968, $P < 0.001$ at D3, and 0.990, $P < 0.001$ at D4. The AUC for Gal was 0.711, $P < 0.001$ at D1, 0.528, $P = 0.689$ at D2, 0.575, $P = 342$ at D3, and 0.541, $P = 0.679$ at D4. The comparison of ROC curves revealed similar AUC at D1 ($P = 0.269$) and significantly lower AUC for Gal in comparison to NSE at D2-4. Multiple logistic regression revealed that combination of both biomarkers at D1 may predict poor prognosis with a 69% specificity and 84% sensitivity (AUC 0.801; $P < 0.001$) and poor outcome with 100% specificity at D1 can be predicted with a sensitivity of 32.4% (Figure 1).
**Conclusions:** Our results indicate significant predictive value off Gal at 24 h after cardiac arrest. The combination of NSE and Gal may improve prognosis prediction with high predictive value already the first day after collapse.

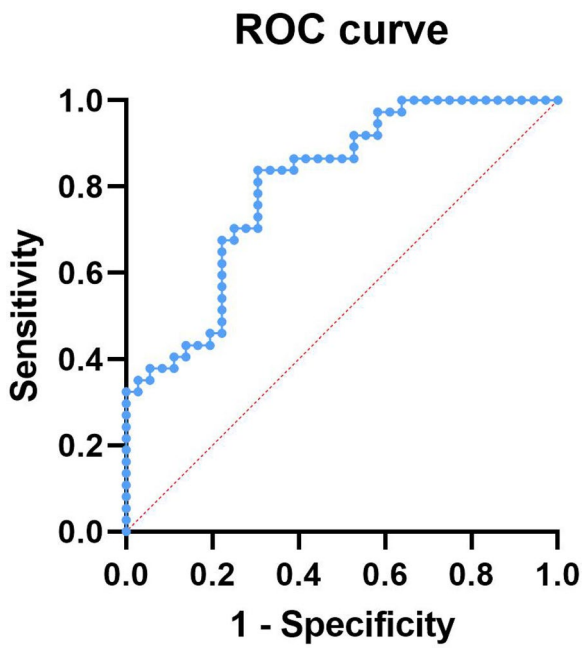

**Fig. 1 (abstract 001206)** ROC curve for the combination of Gal and NSE at D1

*Intensive Care Medicine Experimental* 2024, **12(suppl 1):**001207

**Introduction:** Acute respiratory distress syndrome is one of the most common pathologies in critical care. Once this pathology has been resolved, the integration of various tests during the mechanical ventilation withdrawal protocol allows predicting the successful weaning of the patient. The evaluation of respiratory effort with tools such as ΔPocc will allow us to have more tools to predict a safer weaning from mechanical ventilation.

**Objectives:** To determine the usefulness of ΔPocc within the weaning protocol of patients with acute respiratory distress syndrome (ARDS) in the Intensive Care Unit of a tertiary hospital in Mexico City.

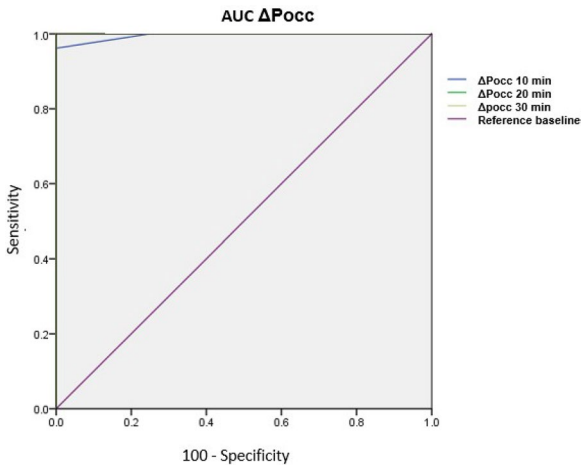
**Methods:** A prospective, analytical, longitudinal and observational study was carried out. The measurement of ΔPocc was obtained in 30 patients in the mechanical ventilation weaning protocol who had ARDS. The measurement was carried out 10, 20 and 30 min after starting the spontaneous ventilation test, in CPAP/Pressure Support (CPAP/PS) mode with FiO2 < 40%, PS 5 cmH2O, PEEP 5 cmH2O for 30 min. AUC were estimated to determine the sensitivity and specificity of ΔPocc in these time intervals.

**Results:** The characteristics of the population are listed in Table 1. It was found that a ΔPocc between −9 and −14 predicts, with a sensitivity of 96% and specificity of 100%, success in extubation, with good correlation at any time of the measurement during the spontaneous ventilation test (Graphic 1).

**Table 1 (abstract 001207)** Characteristics of the population

| | | |
|---|---|---|
| Age | 46 years (± 18 years) | |
| Length of days | 10 days | |
| Days of mechanical ventilation | 9 days | |
| SOFA | 9 points | |
| Weaning | Successful 26 patients<br>Fail 4 patients | |
| | Diaphragmatic dysfunction | 1 patient |
| | Secretions | 3 patients |

**Conclusions:** The ΔPocc is a good predictor to ensure successful weaning and is complementary to other tests to be evaluated during weaning from mechanical ventilation, allowing the evaluation of respiratory effort to be integrated into said protocol.



**Graphic 1 (abstract 001207)** AUC ΔPocc at 10, 20 and 30 min after the spontaneous ventilation test

***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001208

**Introduction:** Septic shock, the most severe form of sepsis, carries high morbidity and mortality. No gold standard for diagnosing sepsis and septic shock exists, which significantly challenges clinical practice. Scoring systems in intensive care units, such as SAPS-3, vary in performance by patient population and complicate distinguishing patients likely to benefit from treatment. Elevated lactate levels (> 2 mmol/L), indicative of septic shock, correlate with shock severity and mortality. However, it remains unclear how lactate measurements—at various stages of the illness—can enhance or refine risk assessment provided by SAPS-3.
**Objectives:** The aim of this study was to investigate the effect of different lactate parameters on the performance of SAPS-3 in patients with septic shock. The primary endpoint was ICU mortality. Furthermore, the assessment of the contemporary mortality of septic shock as well as ideal cutoff values for lactate and SAPS-3 were secondary aims of this study.
**Methods:** Consecutive patients admitted to the participating ICUs of the University Hospital Vienna between January 2017 and December 2019 were screened for septic shock and included if they met the Sepsis-3 criteria within the first 24 ± 4 h of ICU admission. Simple logistic regression was used to test SAPS-3 and lactate as prognostic markers and cutoffs were identified using Youden's index. Multiple logistic regression models were then used to determine the effects of lactate on SAPS-3. ROC curves were plotted and the AUROCs of these models were then compared with that of SAPS-3 alone using DeLong test.
**Results:** The mortality rate of septic shock in this population was 62.12%. Non-survivors had significantly higher SAPS-3 ($p = 0.001$) as well as first lactate, last lactate and peak lactate levels than survivors ($p < 0.001$). The 24-h lactate clearance was lower in non-survivors than in survivors, but the difference did not reach statistical significance (-11% vs. 17%, $p = 0.1$). SAPS-3 and all three measured absolute lactate levels were significant predictors of ICU mortality. Adding each of the three lactate measurements to the SAPS-3 score improved the AUROC in the multiple logistic regression analysis, indicating enhanced predictive accuracy compared to using SAPS-3 alone. However, it was the incorporation of the last lactate value specifically that achieved a statistically significant enhancement, with the AUROC increasing from 70.3% to 80.0% ($p = 0.033$), as shown in the Figure below.

**Table (abstract 001208)** SAPS-3 and lactate

| Characteristic | N | total [1] | ICU mortality | | *p*-value [2] |
|---|---|---|---|---|---|
| | | | Non-survivor, *N* = 41 [1] | Survivor, *N* = 25 [1] | |
| SAPS-3 | 66 | 81 (± 16), [52,122] | 86 (± 15), [59, 122] | 73 (± 14), [52, 108] | **0.001** |
| First lactate (mmol/L) | 66 | 5.8 (± 5.1), [0.9, 22.0] | 7.4 (± 5.9), [1.7, 22.0] | 3.3 (± 1.7), 2.9 [0.9, 6.8] | **< 0.001** |
| Last lactate (mmol/L) | 58 | 4.3 (± 4.3), [0.9, 18.0] | 5.8 (± 4.9), [1.2,18.0] | 2.4 (± 2.2), [0.9, 9.6] | **< 0.001** |
| Peak lactate (mmol/L) | 58 | 6.1 (± 4.3), [2.1, 22.0] | 7.6 (± 4.8), [2.4, 22.0] | 4.3 (± 2.3), [2.1, 9.7] | **< 0.001** |
| 24-h lactate clearance (%) | 58 | 1 (± 74) | -11 (± 78) | 17 (± 68) | 0.10 |

[1] mean (± SD), [min., max.]
[2] First, last and peak lactate were transformed by log to perform t-test

**Conclusions:** Our analysis revealed an improved predictive capacity of SAPS-3 when combined with lactate levels for patients in septic shock, compared to the use of SAPS-3 in isolation. Notably, lactate measurements taken after 24 h significantly enhanced the accuracy of outcome predictions.

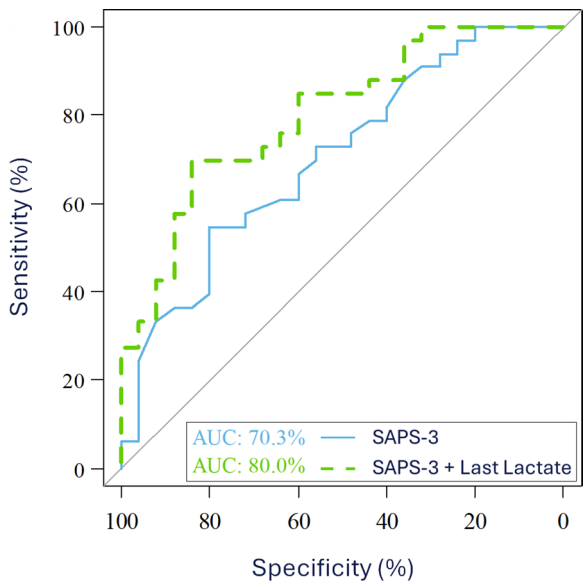

**Fig. (abstract 001208)** SAPS-3 ± last lactate (ROC curve), $N = 58$. Blue curve—SAPS-3. Green curve—SAPS-3 + last lactate

### Patients treated with therapeutic plasma exchange (TPE) in critical care: a single centre study of alterations in haemostatic and biochemical parameters during treatment

A. Chubb[1], F. Baldwin[2]
[1]Anaesthetics, University Hospitals Sussex, Brighton, United Kingdom; [2]Intensive Care, University Hospitals Sussex, Brighton and Hove, United Kingdom
**Correspondence:** A. Chubb
***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001209

**Introduction:** Therapeutic plasma exchange (TPE) is a treatment used in the Intensive Care Unit (ICU) for a variety of disease states in an attempt to remove harmful molecules from the body. It is well established that during treatment, TPE alters the haemostatic balance through the removal of non-target components such as platelets and coagulation proteins, as well as by the use of circuit anticoagulant and haemodiluting replacement fluids.1 We performed a retrospective analysis of patients undergoing TPE in our ICU with the aim of evaluating the effect of TPE on standard laboratory parameters.
**Objectives:** To observe the indications, practices and outcome of TPE in a tertiary care ICU and its effect on the haemostatic and biochemical parameters of patients undergoing treatment.
**Methods:** We conducted a single-centre retrospective analysis of all patients ($N=26$) who underwent TPE between February 2023 and January 2024. Data relating to demographics, diagnosis, number of sessions and type of replacement fluid were collected. We analysed differences in admission international normalized ratio (INR), platelet count (109/L), serum-adjusted calcium (mmol/L) and albumin levels (g/L) with those measured during treatment.
**Results:** A total of 26 patients were evaluated. There were 11 males and 15 females who had a mean age of $56.9 \pm 21$ years. 129 TPE sessions were recorded. Indications for treatment are shown in Figure 1. Mean length of stay was $11.5 \pm 9.5$ days. All patients received 5% human albumin solution as their replacement fluid and all circuits were anticoagulated with heparin. During TPE treatment, compared to admission bloods, we found a significant change in the mean level of several parameters. Mean platelet counts were significantly reduced during TPE (158 vs 280, $p<0.0001$), which represents an average reduction from admission of $43\% \pm 19.4$. Mean albumin levels were also reduced (27 vs 36, $p<0.0001$), as were serum calcium levels (2.1 vs 2.4, $p<0.0001$). There was a significant difference in admission INR to the highest level during treatment with an average increase of $26\% \pm 20$. Of note, we found no correlation with number of TPE sessions and severity of abnormal results. No major bleeding complications were reported.
**Conclusions:** As with previous studies, in this cohort, we demonstrated that TPE treatment alters haemostatic markers, electrolyte and albumin levels. In particular, we found a marked universal reduction in platelet counts during treatment. This is likely to be due to the inadvertent removal of platelets due to the mechanical processing of blood in the extracorporeal circuit itself1. Unlike previous studies, we found no correlation with measured coagulopathy and the number of TPE sessions or type of fluid replacement used2. Despite the observed changes in biochemical parameters TPE-associated bleeding complications are low. Prospective studies are needed to determine the multiple factors causing these blood abnormalities and to evaluate the impact of these on patient outcomes.

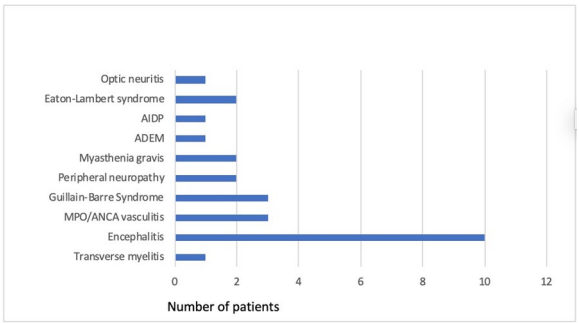

**Fig. 1 (abstract 001209)** Indications for TPE treatment on our ICU. Acute disseminated encephalomyelitis (ADEM). Acute inflammatory demyelinating polyneuropathy (AIDP) .

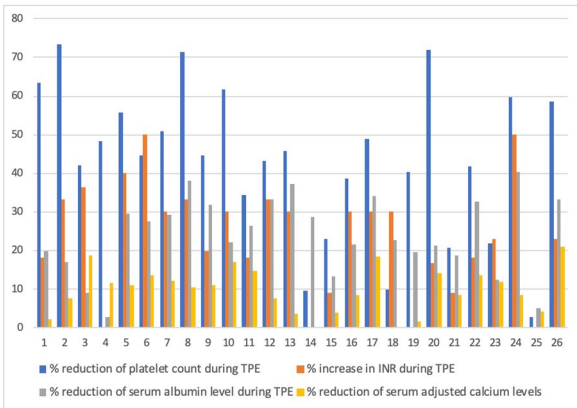

**Fig. 2 (abstract 001209)** Graph to show the percentage (%) reduction of platelet count, serum albumin and serum-adjusted calcium levels, and % increase in INR during TPE treatment from admission baseline bloods

***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001210

**Introduction:** Cytoreductive surgery (CRS) and hyperthermic intraperitoneal chemotherapy (HIPEC) are therapies employed in patients with peritoneal carcinomatosis associated with digestive cancers, ovarian cancers, and primary peritoneal malignancies. While effective, they carry significant risks, including considerable morbidity and mortality. Hematological toxicity is a poorly defined complication, given limited research on the subject, and reported outcomes exhibit wide variability, with incidences ranging from 2 to 38% (1,2,3). Determining the frequency of its occurrence and understanding its impact throughout the postoperative period may be crucial for implementing preventive strategies within post-surgery recovery protocols.
**Objectives:** Assessing the influence of hematological complications in patients admitted to the ICU following the postoperative period of cytoreductive surgery and HIPEC.

**Methods: Design**
Prospective observational study conducted in a Spanish Intensive Care Unit (ICU) focusing on patients admitted following cytoreductive surgery and HIPEC from January 2013 to December 2023.

**Study variables**
The recorded data included age, sex, cancer type, severity upon ICU admission (APACHE II and SOFA scores), daily complete blood count and coagulation times, hemorrhagic complications, ICU mortality, and length of stay.
We defined leukopenia as $<4000/\mu l$, thrombocytopenia as $<150{,}000/\mu l$, anemia as hemoglobin $\leq 10$ g/dl, coagulopathy as INR $\geq 1.3$ and/or APTT $>37$ s, and hypofibrinogenemia as $<200$ mg/dl.
**Analysis**
Qualitative variables were described using counts and percentages, while quantitative variables with a normal distribution were presented as mean $\pm$ standard deviation. For quantitative variables with a non-normal distribution, median (interquartile range) was utilized for description.
**Results:** 123 patients were admitted to the ICU during the selected period, of which 61% of the total were men. The mean age was $59.5 \pm 10.5$ years, with an average APACHE score of 8.5 (6.0–12.0) and a Charlson index of 6. Of the sample, 15.4% (19) had gynecological cancer and 84.6% (104) had digestive cancer.
112 (91%) patients experienced some form of hematological complication: 12 (9.7%) had leukopenia, 59 (47.6%) had thrombocytopenia, 71 (57.3%) had prolonged coagulation times, 76 (61.3%) had anemia, and 12 (9.7%) had hypofibrinogenemia.
Only 11 (15%) patients had hemorrhagic complications: 45% had bleeding related to surgical drains, 45% had hematuria, and 10% had gastrointestinal bleeding. All of these were managed conservatively.
Only 17 (19%) patients required blood transfusions, and 1 (<1%) required platelet transfusion.
The average length of stay in the ICU was 5 (4–5) days. ICU mortality was 0.8%, but it was not associated with hemorrhage.
**Conclusions:** In our research, we observed that 91% of patients undergoing CRS and HIPEC experienced hematological complications during the immediate postoperative period. The majority of these complications were not severe and resolved spontaneously, without a significant impact on mortality or length of hospital stay.

***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001212

**Introduction:** Transcranial Doppler ultrasound is used for evaluation and monitoring in neurocritical patients in most intensive care units. Currently, it has important applications to determine cerebral vasomotor reactivity, monitoring flow velocities in real time, in addition to being a diagnostic complement in the daily monitoring of neurocritical patients. Today it is known to be a bedside tool that provides real-time information on cerebral hemodynamics.
**Objectives:** To evaluate the cerebral hemodynamic behavior measured by ultrasound after changing position in prone position in patients with ARDS.
**Methods:** An observational, analytical, prospective study was carried out, in the intensive care unit hospital in Mexico, over a period of nine months. Patients with a diagnosis of ARDS who required a prone position were included. Ultrasonographic measurements of the middle cerebral artery (MCA) were performed; systolic velocity (SV), diastolic velocity (DV), mean velocity (MV), pulsatility index (PI), intracranial pressure (ICP), resistive indices (IR) and cerebral perfusion pressure (CPP) by Bellner formula, before of the prone position, during the prone position, and one hour afterward.
**Results:** Measurements were obtained from 26 patients diagnosed with ARDS who required a prone position. The Kolmogorov–Smirnov test was applied, showing normality of the sample. The admission diagnoses were 3 neurocritical patients plus ARDS (11.5%) and 23 had ARDS alone (88.5%). Using the ANOVA test of repeated means, statistical significance was evident during the measurements carried out before and during prone, but with stability after the first hour of prone, remaining within physiological ranges. An increase in the flows of the left and right MCA of the SV, RV and MV was evident after performing the prone position ($p<0.001$), as well as an increase in IP, IR and CPP ($p<0.005$), however, remained stable towards the first hour of the maneuver. In the case of ICP, a decrease in it was evident at the time of the prone position, of up to 1.1 mmHg ($p<0.005$). (Table 1).

**Table 1 (abstract 001212)** Measurement of cerebral flows in the MCA ($n = 26$)

| Variable | Before-prono Media (SD) | Prono Media (SD) | Prono + 1 h Media (SD) | *p*-value |
|---|---|---|---|---|
| MCA right | | | | |
| • SV | 78.15 (2.62) | 80.92 (2.42) | 82.11 (2.27) | < 0.001 |
| • DV | 36.4 (2.62) | 39.65 (2.38) | 40.73 (2.21) | < 0.001 |
| • MV | 50.33 (2.38) | 53.41 (2.24) | 54.52 (2.06) | < 0.001 |
| • IP | 0.88 (0.069) | 0.81 (0.051) | 0.78 (0.047) | < 0.005 |
| • ICP | 8.40 (0.756) | 7.5 (0.560) | 7.3 (0.517) | < 0.005 |
| • IR | 0.539 (0.026) | 0.515 (0.021) | 0.507 (0.019) | < 0.005 |
| • CPP | 68.2 (1.68) | 68.3 (1.14) | 70.6 (1.08) | < 0.005 |
| MCA left | | | | |
| • SV | 78.30 (2.78) | 81.65 (2.51) | 80.57 (2.24) | < 0.001 |
| • DV | 38.19 (2.42) | 39.65 (2.38) | 40.73 (2.21) | < 0.001 |
| • MV | 51.56 (2.39) | 54.73 (2.31) | 54.52 (2.06) | < 0.001 |
| • IP | 0.82 (0.061) | 0.77 (0.048) | 0.73 (0.039) | < 0.001 |
| • ICP | 7.76 (0.661) | 7.25 (0.524) | 6.81 (0.431) | < 0.005 |
| • RI | 0.518 (0.024) | 0.501 (0.020) | 0.487 (0.017) | < 0.005 |
| • CPP | 68.8 (1.66) | 68.7 (1.13) | 71.14 (1.01) | < 0.005 |

SV: systolic volume, DV: diastolic volume, MV: media velocity, IP: pulsatility index, ICP: intracranial pressure, RI: resistive index, CPP: cerebral perfusion pressure

**Conclusions:** The prone position in patients with ARDS, regardless of its origin, presented changes in cerebral hemodynamics, although these changes were not outside physiological ranges. Furthermore, in terms of ICP, showed that after the prone position, there is a decrease in it, so we could consider it as something beneficial for patients with ARDS.

***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001215

**Introduction:** There is a lack or solid data about the endotoxin hemoadsorption (ET-HA) in patients with septic shock (SS) and severe multiorgan dysfunction (MODS) with extreme endotoxin activity (EAA, EAA $\geq$ 0.9).

**Objectives:** To analyze the efficacy of ET-HA in reducing EAA in patients with SS and MODS with extreme EAA.

**Methods:** This is a single-center, observational and retrospective study (January 2018 to December 2023). Inclusion criteria: patients with septic shock (Sepsis 2) and multiorgan dysfunction with EAA $\geq$ 0.9 who were treated with ET-HA. We evaluated the endotoxin activity with the Endotoxin Activity Assay (Spectral Medical Inc, Canada). EAA was measured at the first 24 h of evolution of septic shock, before the ET-HA (EAApreET-HA) and also in the following 18-20 h (EEApostET-HA). Hemodynamic, organ dysfunction and inflammatory parameters were recorded. ET-HA (Toraymyxin™) was performed in the first 24 h of septic shock evolution. In patients in whom the EAA control was less than 0.6, the second session of HA-ET was not performed. The data have been expressed a "n" (%) if they are categorical and as median (interquartile range) or mean (standard deviation) if they are quantitative. The study was approved by the Clinical Research Ethics Committee (PR(AG)336/2016).

**Results:**

During the described period, 33 HA-ETs were performed in patients with septic shock, MODS and EAA $\geq$ 0.6. In 10 patients, the EAA was $\geq$ 0.9: 60% men, mean age 57 (13) years, SOFA 11 (2) points, APACHE II 32 (9) points, lactate 12 (3.9) mmol/L. In half of the patients, the focus of infection was respiratory and in the other half abdominal. Table 1 summarizes other characteristics of the included patients. The EAApreET-HA was 1.17(0.37) and EAApostET-HA 0.34 (0.28). A second session of HA-ET was necessary in only 3 patients. Hospital mortality and ICU mortality were 60%.

**Conclusions:** In our series, HA-ET in patients with SS, MODS and extreme EAA has been associated with an improvement in EAA levels.

### Impact of the development of electrolyte and renal complications in the immediate postoperative period of cytoreduction surgery and hyperthermic intraperitoneal chemotherapy

D. R. Beltran[1], M. C. Pintado Delgado[1], A. B. Oñoro Morales[1], V. Rubio Uriarte[1], M. Jimenez[1], D. Molina[1], I. Seises García[1], J. Vejo[1], J. Lujan Varas[1], E. Nevado Losada[1]
[1]Intensive Care Unit, Hospital Príncipe de Asturias, Alcalá de Henares, Spain
**Correspondence:** D.R. Beltran
***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001217

**Introduction:** The combination of hyperthermic intraperitoneal chemotherapy (HIPEC) with cytoreductive surgery (CRS) represents the primary treatment for selected patients with peritoneal malignancies. However, HIPEC carries a moderate to high morbidity and mortality, including the possibility of developing postoperative acute kidney injury, with a prevalence that varies widely between 1 and 48% (1,2,3). Identifying the frequency of this complication and understanding its impact throughout the postoperative period is essential to implement preventive strategies within surgical recovery protocols.
**Objectives:** To determine the influence of electrolyte and renal complications in patients admitted to the ICU after postoperative cytoreduction and HIPEC surgery.
Methods. Design
Prospective observational study in a Spanish polyvalent ICU of patients admitted after cytoreduction and HIPEC from January 2013 to December 2023.
Data recorded were age, sex, type of cancer, severity at ICU admission (APACHE II and SOFA scores), complete biochemistry panel, need for CRRT, ICU mortality and length of stay.
We defined ARF as an increase in serum creatinine (Cr) of $\geq$0.3 mg/dl within 48 h after surgery. Electrolyte disturbances were defined as all electrolyte disturbances outside the laboratory range. Polyuria was defined as urine output greater than 3 L/day.
Analysis
Qualitative variables are described as number and percentages, quantitative variables with normal distribution as mean $\pm$ S.D., quantitative variables with non-normal distribution as median (interquartile range).
**Results:** 123 patients were accepted in the ICU during the chosen period, of which 61% of the total were male, the mean age was 59.5 $\pm$ 10.5 years and the mean APACHE was 8.5 (6.0–12.0) and a Charlson index of 6. Of the sample, 15.4% (19) were cancer of gynaecological origin and 84.6% (104) were of digestive origin. 119 (96%) patients had some type of ionic alterations, all asymptomatic: hyponatraemia 28 (22.8%), hypernatraemia 4 (3.2%), hypokalaemia 51 (41.1%), hyperkalaemia 3 (2.4%), hypomagnesaemia 31 (25.0%), hypermagnesaemia 10 (10.0%), hypophosphataemia 29 (23.4%), hypocalcaemia 107 (86.3%) and hypercalcaemia 1 (0.8%).
Only 6 presented ARF (4.9%) and only 1 (0.8%) required CRRT.
Polyuria was present in 106 (85.4%).
Mean ICU stay was 5 (4–5) days.
ICU mortality was 0.8% but was not related to electrolyte disturbances or acute renal failure.
**Conclusions:** In our study, we observed that patients undergoing CRS and HIPEC very commonly experienced some type of ionic complication (96%) with a low frequency of renal failure (4.9%) during the immediate postoperative period. Most of these complications were not severe and resolved spontaneously, with no significant impact on mortality or length of hospital stay.

**Introduction:** Organ transplantation saves thousands of lives around the world and it is one of the greatest medical advances of the twentieth century. These organs can be harvested from brain dead donors (DBD) or circulatory death donors (DCD), originally known as non-heart-beating donation. Controlled cardiac arrest donation after withdrawal of life support therapy—Maastricht classification type III donors—is expanding and has been demonstrated as an important source of viable organs, but in Portugal this is not yet legally approved. Therefore, despite the excellent results and improvements implemented in recent years in Portuguese organ donation, there are limitations when compared to other European countries such as Spain.
**Objectives:** The aim of this study was to estimate the number of patients that could have been possible organ donors in the intensive care unit of a tertiary hospital, if Maastricht III category was approved in Portugal.
**Methods:** We used the clinical records of patients admitted to the intensive care unit of a tertiary hospital in Portugal between January 1st and December 31st of 2023. Patients with death associated with limitation of life support therapy, due to critical and irreversible illness and without unexpected cardiac arrest or hemodynamic instability, were selected. Finally, all patients who presented a contraindication to organ donation were excluded (for example, chronic or acute pathology compromising the donation, uncontrolled infection or hematological dyscrasia/vascular disease making cannulation impossible).
**Results:** Of the 699 patients admitted to the intensive care unit of a tertiary hospital between January 1st and December 31st of 2023, a total of 36 were considered possible organ donors in Maastricht category III. The median age was 66.0 years [P25 56.3 years and P75 77.0) and 52.8% ($n = 19$) were female. The main diagnosis at hospital admission was non-traumatic intracerebral hemorrhage in 13 (36.1%), ischemic stroke in 8 (22.2%), traumatic brain injury in 8 (22.2%), post-anoxic encephalopathy in 5 (13 0.9%), spinal cord trauma in 1 (2.8%) and meningo-encephalitis in 1 (2.8%) patient.
**Conclusions:** Although not all potential donors progress to effective donation and transplantation, the approval of donation in controlled circulatory arrest in Portugal could increase the number of organs (especially kidney and liver) and consequently reduce the amount of patients waiting for transplantation.
In the future, we expect to increase research in this area and predict the benefits of including Maastricht III category for organ donation in the norms and laws of our country. We also aim to improve protocols and discuss related ethical issues, as well as health literacy of the Portuguese population.

## Acute renal failure and electrolyte disorders in the immediate postoperative period of cytoreductive surgery and hyperthermic intraperitoneal chemotherapy (HIPEC) with cisplatin

***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001219

**Introduction:** Cytoreductive surgery (CRS) and hyperthermic intraperitoneal chemotherapy (HIPEC) are treatments employed to manage peritoneal carcinomatosis in patients with digestive, ovarian, and primary peritoneal cancer. The most commonly used treatment regimens include cisplatin and/or mitomycin. Given the known adverse effects of cisplatin in systemic therapies, it is likely to contribute to the development of acute kidney injury and electrolyte imbalances in the postoperative period (1,2,3). On the other hand, other chemotherapy agents such as mitomycin often exhibit a more favorable safety profile regarding renal complications and electrolyte imbalances (3,4). Identifying the frequency of these complications, associated factors, and understanding their impact throughout the postoperative period could be essential for implementing preventive strategies within post-surgical recovery protocols.
**Objectives:** To evaluate whether the use of cisplatin in HIPEC therapies was associated with a higher incidence of renal and electrolyte complications in the immediate postoperative period compared to other therapies such as mitomycin.

**Methods: design**
This is a prospective observational study in a Spanish polyvalent ICU of patients admitted after undergoing cytoreduction and HIPEC from January 2013 to December 2024.

The recorded data included age, sex, type of cancer, severity upon admission to the ICU (APACHE II and SOFA scores), complete biochemistry panel, need for RRT, ICU mortality, and length of stay.
We defined AKI as an increase in serum creatinine (Cr) of $\geq 0.3$ mg/dl in the 48 h following surgery. Electrolyte abnormalities were defined as any values outside the laboratory range.
Analysis
Quantitative variables are described with mean and standard deviation or with median and interquartile range using the Mann–Whitney U test for analysis. For categorical variables, percentages were calculated and compared using Fisher's exact test. In all cases, values of $p < 0.05$ were considered statistically significant.
**Results:** A total of 123 patients were included, of whom 115 had electrolyte abnormalities. 31 (49.2%) were males. The mean age was $59.32 \pm 10.54$ years. 104 (84.6%) had digestive cancer and 19 (15.4%) had gynecological cancer. The mean APACHE II and SOFA scores upon admission to the ICU were 8.5 (6–12) and 2 (1–3), respectively, with a Charlson index of 6, without statistically significant differences. It was observed that patients treated with cisplatin had a significantly higher positive fluid balance compared to those treated with mitomycin, with a statistically significant difference.
There were no differences in the need for mechanical ventilation upon admission, the use of amines, and the need for blood products.
The mean ICU length of stay was 5 (4–5) days.
ICU mortality was 0.8%, but it was not related to electrolyte abnormalities or the presence of renal failure.
**Conclusions:** In our research, we observed that the use of cisplatin in patients undergoing CRS and HIPEC was not associated with a higher incidence of renal complications compared to those treated with mitomycin. Ionic disturbances were common in both groups, with hypokalemia and hypocalcemia being the most prevalent. The use of cisplatin

was statistically significantly associated with hypomagnesemia found in this group of patients.

**Table 1 (abstract 001219)** .

| Renal complications | All (123) | Cisplatin (53) | Mitomycin (70) | P |
|---|---|---|---|---|
| Need of RRT | 0 | 0 | 0 | |
| Hematuria | 9 (7.4%) | 3 (5.8%) | 6 (8.6%) | 0.731 |
| FRA AKIN | 6 (4.9%) | 3 (5.7%) | 3 (4.3%) | 1.000 |

**Table 2 (abstract 001219)** .

| Electrolytes abnormalities | All | Cisplatin | Mitomycin | P |
|---|---|---|---|---|
| | 115 (95.8%) | 49 (94.2%) | 66 (97.1%) | 0.651 |
| Hyponatremia | 27 (22.1%) | 10 (18.9%) | 17 (24.6%) | 0.633 |
| Hypernatremia | 4 (3.3%) | 1 (1.9%) | 3 (4.3%) | 0.156 |
| Hypokalemia | 50 (40.7%) | 31 (58.5%) | 19 (27.1%) | 0.000 |
| Hyperkalemia | 3 (2.4%) | 0 (0.0%) | 3 (4.3%) | 0.258 |
| Hypomagnesemia | 31 (25.2%) | 19 (35.8%) | 12 (17.1%) | 0.018 |

**Introduction:** Post-operative complications and clinical outcome are important quality indicators of surgical intensive care unit (ICU). With improvement in surgical and anaesthesia services, post-operative (PO) complication rate has been shown to come down significantly. Anticipating PO complications can be challenging as most of the predictive scores (ASA, P-POSSUM) are known to overestimate morbidity and mortality. APACHE 4 and APS are scoring systems validated in medical ICU patients to predict prognosis depending on its value in first 24 h. Therefore, this study hypothesized that PO APACHE 4 and APS scores on first 48 h can be predictive of PO outcome in terms of ICU stay and mortality.
**Objectives:** Aim of this retrospective study was to evaluate PO severity scores as predictive tools for PO outcome. The objective of the study is to evaluate association of PO APACHE 4 and APS score (Day 1 and Day 2) with PO mortality and ICU stay.
**Methods:** This is a retrospective observational single-center study conducted in 11 bedded onco-surgical ICU of a tertiary care cancer center. We had collected data from January 2023 to June 2023, of all post-surgical patients, admitted to ICU either for organ support (mechanical ventilation or vasopressor support) or for close observation. Patients requiring 3 or more days of ICU stays were included in the study protocol. APACHE 4 and APS were calculated for all these patients on post operative day 1 and day 2 and depending on that value, predicted mortality and ICU stay were calculated. Predicted mortality and ICU stay were then compared with actual mortality and ICU stay for all these patients.
**Results:** During this 6-month period, 117 patients were included in the study. Distribution of patients according to months have been shown in Figure 1. For PO Day 1, mean (Std) APACHE 4 score of our patients was 47 (13) and mean (Std) APS score was 29 (12). For PO Day 2, mean (Std) APACHE 4 score was 44 (11) and mean (Std) APS score was 26 (8). Anticipated ICU stay according to PO Day 1 severity score (4.0 days) is more representative of actual ICU stay (4.26 days) compared to that of PO Day 2 (3.0 days). On the other hand, predicted mortality as per PO Day 2 score (5 deaths) is more representative of actual mortality (5 deaths). PO Day 1 score overpredicts mortality (8 deaths). Figure 2 depicts the month wise distribution of (a) mean APACHE 4 score, (b) mean APS score and (c) estimated and actual length of ICU stay. Subgroup analysis of patients with prolong ICU stay had shown that surgical complications had happened mostly on day 3 and beyond.
**Conclusions:** Severity scores (APACHE 4 and APS) on PO Day 1 can be representative of PO ICU stay, whereas severity scores on PO Day 2 can corroborate with PO mortality. Larger sample size is needed to assess statistical test of significance. Severity scores (APACHE 4 and APS) on PO Day 3 can be more contributory to pick up surgical complications.

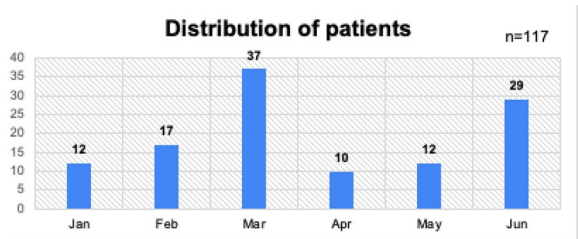

**Fig. 1 (abstract 001221)** Distribution of patients according to months within study period ($n = 117$)

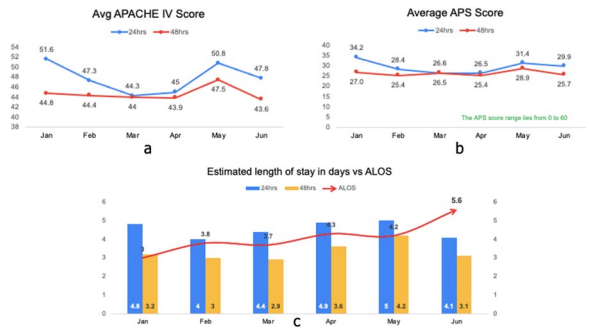

**Fig. 2 (abstract 001221)** Distribution of (a) mean APACHE 4 score, (b) APS score and (c) estimated and actual length of ICU stay according to months within study period ($n = 117$)

**Introduction:** Venous thromboembolism prophylaxis is increasingly performed in the ICU. Enoxaparin, a low-molecular weight heparin, is frequently used for this purpose. Enoxaparin follows first-order kinetics and is eliminated primarily by the kidneys. Increased renal clearance is frequently observed in critically ill patients; consequently, standard dosing of enoxaparin can lead to treatment failure.
**Objectives:** To determine the influence of increased creatinine clearance on anti-Xa activity levels in critically ill patients.
**Methods:** Prospective and observational study at a tertiary university hospital, between October 2022 and March 2024. Critically ill adult patients who received a prophylaxis dose of 40 mg/day of enoxaparin were included. Anti-Xa activity was measured at day four (D4) and day seven (D7) after starting prophylaxis. Prophylactic levels were considered between 0.2 and 0.5 IU/mL. Increased creatinine clearance was defined as 8-h measured urinary creatinine clearance (CLCR8h) above 150 ml/min. Patients were divided into two groups according to this cutoff. Patients with CLCR8h < 60 mL/min were excluded.
**Results:** Sixty-four patients were included. On D4, 25% of patients had increased creatinine clearance (group 1) showing a median CLCR of 173 mL/min and on D7, 21% had increased creatinine clearance and a median CLCR of 192 mL/min. Group 1 was younger (46 vs. 64 y; $p < 0.05$); however, both groups showed similar SOFA and severity scores. Within groups, anti-Xa activity was 0.21 vs. 0.27 ($p = 0.247$) and 0.27 vs. 0.33 ($p = 0.114$) in D4 and D7, respectively. When considering all the measurements in the two time-point (D4 and D7, $n = 93$), no correlation was found between Anti-Xa activity and CLCR8h. The rate of target attainment was 62.5% vs. 77.1%, at D4 and 100% vs. 91.3% at D7, respectively, for group 1 and 2, not statistically significant.
**Conclusions:** In ICU setting, increased renal function above 150 mL/min seems to make more difficult reaching the target for anti-Xa activity. In patients exhibiting this condition, the anti-Xa activity should be monitored, in order to minimize the risk of therapeutic (prophylactic) failure.

***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001227

**Introduction:** Patients admitted in ICU present hypercatabolism, proteolysis and muscle loss during their ICU stay. Those patients may also present testosterone deficiency. Testosterone is one of the anabolic hormones of the organism. Several studies have demonstrated the benefit of Testosterone's administration in severe burns patients to reduce the proteolysis and improve their rehabilitation. The administration of Testosterone Skin Gel (AndroGel®) has not been studied in ICU until nowadays. Pharmacokinetics data are also missing.
**Objectives:** The purpose of this pilot study called TestICUs-1 is to evaluate the pharmacokinetics and tolerance of the 14-day administration of 101.25 mg of testosterone for men and 25.25 mg for women.
**Methods:** This is an open, monocentric, randomized controlled study achieved in the medical intensive care of Clermont Ferrand University Hospital. Patients admitted for shock and intubated for at least two days were included. Patients with PSA > 4 ng/mL were excluded. The primary outcome was the rate of patients with serum testosterone concentration within norms at days 4, 7, 10 and 14

(Testosterone > 280 ng/mL for male and > 12 ng/dL for female). TestICUs-1 trial was approved by the French ethical community (N°18044-RIPH1, CPP: "comité de protection des personnes", Ile de France, France).
**Results:** Finally, 30 patients were included (14 in the placebo group and 16 in the interventional group). Median age was 66.1 y.o.; 19 (63.3%) patients were males; SAPS II was 63.5 and hospital mortality rate was 53.3% ($N = 16$). On inclusion, testosterone concentration was 43 ng/dL [13.5; 66] with similar concentrations in both groups (45 [15; 68] in placebo and 40 [12; 64] in interventional); at days 4, 7 and 10, testosterone concentrations were higher in the interventional group (Day 4: placebo: 22 [13.5; 40.5] versus intervention: 68 [46; 86]; $p < 0.01$). At day 4, only 4/25 (16%) of the patients get their Testosterone in normal range with no significant difference between placebo and intervention (Placebo: 1/12 (8.3%) versus 3/13 (23.1%), $p = 0.32$). Similar results were obtained at days 7, 10 and 14. Only female presented testosterone in normal range after intervention but not male. Occurrence of adverse events were similar in both the groups.
**Conclusions:** During ICU stay, all the patients presented hypotestosteronemia. After supplementation, concentrations of testosterone increased compared to placebo but became in normal range only for the female. Androgel with those dosage can be administered safely and its impact on functional outcome should be assessed.

***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001229

**Introduction:** Assessing readiness for extubation is challenging in critically ill patients. Effective coughing is essential but hard to quantify. Ultrasound can help predict high-risk mechanical ventilation liberation failure by assessing abdominal muscle activation during coughing in ventilated patients.
**Objectives:** This study aims to 1) evaluate the effectiveness of using abdominal muscle ultrasound measurements to predict the success of weaning and 2) investigate the relationship between abdominal muscle weakness (ABSAW) and critical illness-associated diaphragm (DD) and limb (ICUAW) weakness and their impact on weaning outcomes.
**Methods:** The study included critically ill intubated or tracheostomized patients mechanically ventilated for over 48 h. The clinical examinations were conducted during the first spontaneous breathing trial (SBT, Pressure support 6 and PEEP 6). As previously described (1), the occurrence of ABSAW was assessed by ultrasound using the combined abdominal muscles thickening fraction during cough (TFabs) of three muscles: rectus abdominis (RA), transversus abdominis (TrA), and internal oblique (IO). ABSAW was defined as TFabs = TFcough, RA + TFcough, TrA + TFcough, IO, less than 127%. DD was defined as a diaphragm thickening fraction (TFdi) lower than 20% (2). ICUAW was defined as usual: a Medical Research Council Scale score (MRCs) score < 48 or a simplified peroneal nerve test (PENT) of less than 5.26 mV in uncooperative patients (3; 4). SBT failure was reintubation or reconnection to ventilator within 48 h. Liberation failure is defined as dependency on a ventilator for more than 7 days following the first SBT. Other data collected included admission diagnosis, clinical data, and outcome.
**Results:** 37 patients were recruited; 21 patients (57%) had a successful SBT, and 17 (46%) failed liberation at 7 days. Consistent with the literature, most patients presented with some degree of weakness, with ABSAW diagnosed in 30 (81%), ICUAW in 27 (73%), and DD in 20 (54%), Table 1. ABSAW patients had higher liberation failure probability (OR 6.86, CI 1.00–137.99, $p$ 00.091) but not SBT failure (OR 0.17, CI 0.01–1.14, p 0.116), Figure 1; liberation failure was only marginally significant. TFabs were unrelated to ICUAW (OR 0.49, CI 0.09–2.01, p 0.350) or DD (OR 0.01, CI -0.9–0.92, $p$ 0.987). ICUAW is related to successful SBT ($p = 0.003$) and liberation failure ($p = 0.007$). ICUAW and DD increase the probability of reintubation-reconnection (OR 10.18, CI 1.51–204.78) but not DD alone. Patients with ABSAW have a higher risk of liberation failure when both ICUAW and DD are present (OR 7.67, CI 0.77–76.3, $p$ 0.082).
**Conclusions:** These preliminary results indicate that ABSAW is associated with a higher reintubation-reconnection rate within 7 days. Small sample sizes and weak patients may have caused the lack of statistical significance. We are increasing the sample size to confirm the TFabs predictive validity for weaning failure.

**Introduction:** Endovascular treatments, like transaortic valve implantation (TAVI), on high-risk cardiovascular patients has improved their survival and quality of life and decreased the morbidity compared to classical surgery. However, is not free of complications, specially due to a high median age and comorbidities. One of the most frequent is the electrocardiographic (EKG) alterations, some of which may require from permanent pacemaker (PM) therapy.
**Objectives:** First, to analyse the percentage of permanent PM in patients who received transaortic valve implantation (TAVI). Second, to identify possible risk factors (RF) associated with this complication.
**Methods:** This is a retrospective observational 36-month study (years 2021 to 2023) who received TAVI in our University Second Level Hospital in Granada (without Cardiac Surgery). The admission and procedure was supported by intensive care physicians in our cardiologic intensive care unit (cICU).
Variables studied: demographic, previous comorbidities, EKG pre- and post-implantation, incidence of permanent PM and mortality rate. We performed a Student T test for continuous variables and a CHI2 test for the categorical variables.
**Results:** We registered 105 TAVI implants, all of them due to severe aortic stenosis. 12 patients (11.4%) had a previous PM. 3 patients (2.85%) died in the operating room. 90 patients entered in our study, in all of them a transitory pacemaker (tPM) was implanted for the procedure via right internal jugular vein.

- 3 patients died during hospital income (3.33%) and 3 during the one-year follow-up (3.33%).
- In 28 (31.11%) patients, a permanent PM was performed before hospital discharge.
- Previous RBBB is related to PM implant (CI 95% 1,545–27,664)
- After surgery, tPM stimulation is related with PM implant (CHI2 40*, not possible CI).

| | Non-PM | PM | *p* | Test |
|---|---|---|---|---|
| Age | 82.64 ± 4.13 | 83.5 ± 3.5 | 0.078 | Student T |
| Cr | 1.15 ± 0.63 | 1.26 ± 0.55 | 0.67 | Student T |
| LVEF < 50% (yes/no) | 83.3% (15)/79.2% (57) | 16.7% (3)/18.2% (15) | 0.693 | X2 |
| IHD (yes/no) | 80.4% (45)/79.4% (27) | 19.6% (11)/20.6% (7) | 0.913 | X2 |

**Conclusions:** The rate for PM implant in our TAVI programme was 31%. In our study, RBBB is the only variable that has been related to permanent PM implant. 12 h after TAVI, transitory pacemaker stimulation due to symptomatic bradycardia is related with the need of dPM.

**Introduction:** Optimal strategy for mechanical circulatory support in acute myocardial infarction (AMI) complicated by ventricular septal defect (VSD) and cardiogenic shock has not been determined. The standard extracorporeal membrane oxygenation (ECMO) increases systemic flow but may have negative effect on left ventricle (LV). The novel ECG-synchronized pulsatile ECMO offers full hemodynamic support and preserves LV function.
**Objectives:** The aim of our study was to compare hemodynamic effects of ECG-synchronized pulsatile and standard continuous ECMO flow in AMI complicated by VSD and cardiogenic shock.
**Methods:** Under general anesthesia and mechanical ventilation in pigs (sus scrofa domestica), AMI was induced by ligation of left anterior descending. VSD was simulated by insertion of 25F cannulas into the left and right ventricles via partial sternotomy, and their extracorporeal connection by 3/8 tubes generating left-to-right shunt. The hemodynamic effect of synchronized pulsatile (P) and standard continuous (C) ECMO flow (2 and 3 L/min) was evaluated by the measurement of left ventricular end-diastolic pressure (LVEDP), mean arterial pressure (MAP), carotid flow (CAR) as a surrogate of total circulatory output, and VSD flow. Data are presented as mean (SD), and $P<0.05$ was considered statistically significant.
**Results:** Eleven animals were used, one died after induction of AMI, and ten pigs completed all study procedures. Baseline LVEDP was 14.0 (2.1) mmHg, MAP 50.0 (11.9) mmHg, CAR 286.2 (27.5) mL/min, and VSD flow 1086.0 (401.6) mL/min (Figure 1). LVEDP was significantly lower with P in comparison to C at 2 L/min (diff −0.8 [1.1] mmHg, $P=0.046$) and at 3 L/min (−0.4 [0.4] mmHg, $P=0.010$) (Figure 1). MAP was significantly higher with P in comparison to C at 2 L/min (+3.5 [2.4] mmHg, $P=0.001$) and at 3 L/min (+3.0 [4.1] mmHg, $P=0.046$) (Figure 1). CAR was significantly higher with P in comparison to C at 2 L/min (+19.7 [8.3] mL/min, $P<0.001$) and at 3 L/min (+22.4 [12.0] mL/min, $P<0.001$) (Figure 1). VSD flow was significantly reduced with P in comparison to C at 2 L/min (−119.4 [79.6] mL/min, $P=0.001$) and at 3 L/min (−87.9 [71.7] mL/min, $P=0.004$) (Figure 1).
**Conclusions:** In the porcine model of AMI complicated by VSD and cardiogenic shock, ECG-synchronized pulsatile ECMO significantly increased systemic arterial blood pressure and carotid artery flow together with the protective effect on LV filling pressure and VSD shunt in comparison to standard continuous flow ECMO.

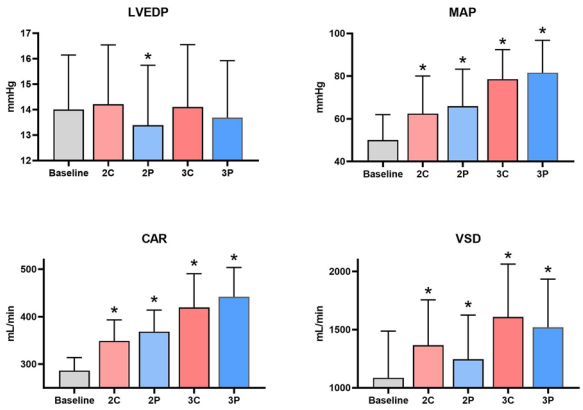

**Fig. 1 (abstract 001231)** Hemodynamic effect of ECG-synchronized pulsatile (P) and standard continuous (C) ECMO flow (2 and 3 L/min) in acute myocardial infarction complicated by ventricular septal defect and cardiogenic shock. LVEDP, left-ventricular end-diastolic pressure; MAP, mean arterial pressure; CAR, carotid artery flow; VSD, ventricular septal defect flow. * $P<0.05$ vs. Baseline

**Introduction:** Lung volume reduction surgery (LVRS) is a beneficial treatment option for COPD patients with severe emphysema, however, with an increased risk of perioperative mortality [1]. Veno-venous extracorporeal membrane oxygenation (vv-ECMO) holds promise in facilitating lung-protective ventilation and rapid recovery of spontaneous breathing postoperatively. The thrombosis and bleeding risk linked with vv-ECMO remains notably high, correlating with a significantly increased mortality rate [2]. Currently, data concerning the thrombosis and bleeding risk during perioperative vv-ECMO for LVRS are limited.
**Objectives:** The primary aim of this study was to examine the incidence of thromboses and bleeding events in patients with advanced emphysema undergoing vv-ECMO as part of lung reduction surgery. We investigated the influence of therapeutic anticoagulation during vv-ECMO initiation compared to the standard of care on the incidence of thrombosis and bleeding events and the occurrence of the individual events between the patients with high-flow and low-flow vv-ECMO.
**Methods:** This retrospective analysis included 30 patients (≥ 18 years) who underwent LVRS with elective perioperative vv-ECMO at Charité—Universitätsmedizin Berlin between July 2019 and February 2023. All patients were admitted to the ICU preoperatively, vv-ECMO (high-flow or low-flow ECMO) was applied on the following day, and lung volume reduction was performed surgically.
One group of patients received therapeutic anticoagulation, i.e., a heparin bolus was administered immediately after vv-ECMO cannulation, adjusted to the initial partial thromboplastin time (PTT) to reach the target PTT range of 60 s. Therapeutic anticoagulation was afterwards continued with heparin perfusion until vv-ECMO removal. The observation period for the occurrence of thrombosis or bleeding events started from ECMO initiation until the end of the ICU stay.
Fisher's exact test was applied to categorical data. The significance level was set at < 0.05. The statistical analysis was performed in Python version 3.6.15.
**Results:** Data from 30 patients were analysed. The median age was 67 [IQR 61–71] years, with 63% being male. Twelve patients received low-flow vv-ECMO, while 18 received high-flow vv-ECMO. The median Charlson Comorbidity Index was 4 [IQR 3–6], and the body mass index was 22.8 [19.6–25.8] kg/m$^2$, respectively. The median duration on vv-ECMO was 26.2 [22.7–50.3] hours.
A total of ten thrombotic events (33%) and five (17%) bleeding events occurred. Four patients (13%) received a heparin bolus immediately after vv-ECMO cannulation. No significant difference in the incidence of bleeding and thrombosis was observed between the group that received therapeutic anticoagulation for vv-ECMO initiation and the group that did not (see Table 1). In addition, no significant difference was observed in either the low-flow or high-flow ECMO groups regarding thrombotic events or bleeding events.
**Conclusions:** One-third of all the patients with severe COPD who underwent perioperative vv-ECMO for LVRS experienced a thrombotic event. There was no difference in thrombotic events or bleeding events depending on an initial heparin bolus or the ECMO flow rate.

**Table 1 (abstract 001232)** Occurrence of bleeding and thrombotic events during perioperative VV -ECMO in patients with lung volume reduction

| Variable | Thrombosis | No Thrombosis | p-value | Bleeding event | No bleeding event | p-value |
|---|---|---|---|---|---|---|
| **Primary analyses** | | | | | | |
| Initial Heparin bolus | 0 (0%) | 4 (100%) | 0.3 | 1 (25%) | 3 (75%) | 0.5 |
| No initial heparin bolus | 10 (38%) | 16 (62%) | | 4 (15%) | 22 (85%) | |
| **Secondary analyses** | | | | | | |
| High-Flow ECMO | 7 (39%) | 11 (61%) | 0.7 | 3 (17%) | 15 (83%) | 1.0 |
| Low-Flow ECMO | 3 (25%) | 9 (75%) | | 2 (17%) | 10 (83%) | |

**Introduction:** Minimally invasive cardiac surgery via right-sided minithoracotomy has advantages over the traditional median sternotomy. However, at the same time, surgeons might have some difficulties in ensuring visualization of the surgical field.
**Objectives:** To choose the optimal ventilation technique during heart valve surgery performed via the right-sided minithoracotomy.
**Methods:** Eighty adult patients were included in non-randomized, retro- and prospective study. All patients underwent heart valve surgery via right-sided minithoracotomy. Peripheral cardiopulmonary bypass with cannulation of the right femoral artery and right femoral vein was carried out. During the surgery besides standard parameters, we monitored invasive blood pressure, central venous pressure, cerebral oximetry, arterial and venous blood gas analysis. Retrospective group included 40 patients with mean age of 52.3 (± 12.4) years, who underwent protective low tidal volume mechanical ventilation in VCV mode with TV 4–6 ml/kg of ideal body weight. Prospective group also included 40 patients with mean age 51.8 (± 13.9) years. They received high-frequency jet injection (HFV) ventilation with MV 10–18 l/min and f 100–120 per min. In the postoperative period, we evaluated the duration of ventilatory support in ICU, length of ICU and hospital stay, incidence of postoperative pulmonary complications.
**Results:** During the surgery, PaO2 was significantly higher in the HFV group compared to the protective ventilator group: 307 (220–352) vs. 106 (90–127.5) $p < 0.0001$ before CPB and 252 (± 98.6) vs. 147 (109.5–183.5), $p < 0.0001$ after CPB. PaO2 to FiO2 ratio (P/F) was also significantly higher during the same stages of the surgery in the HFV group compared to the protective ventilator group: 623 (450–714) vs. 226.9 (± 77.1) $p < 0.0001$, 506.3 (199.5) vs. 260 (200.5–358), $p < 0.0001$, respectively. In addition, we found out significant differences between groups in PaCO2 levels, 47.5 (38–54) vs. 42 (38.3–44), $p = 0.0162$ and 48 (39–54) vs. 39.8 (± 5.1) $p = 0.0005$, respectively. Visualization of the operative field was better in the HFV group compared to the protective ventilation group and was rated as good in 80% of cases. There were no significant differences between the groups in the number of postoperative pulmonary complications, as well as the duration of postoperative ventilatory support and length of ICU stay.
**Conclusions:** Use of high-frequency jet injection ventilation during heart valve surgery via right-sided minithoracotomy allows to ensure adequate oxygenation and avoid hypoxemia. Meanwhile, it does not have a negative impact on visualization of operative field and does not lead to the increase of postoperative complications.

***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001234

**Introduction:** Diaphragmatic weakness is present in up to 60–80% of the critically ill patients and prolonged invasive mechanical ventilation (MV) is considered one of the main causes. It appears early after initiation of invasive MV and the degree of diaphragmatic weakness is related to the duration of MV and the use of mandatory modalities. To date, there are few treatment strategies to counterbalance diaphragmatic weakness, and these are rarely applied in sedated patients on continuous mandatory ventilation. Phrenic nerve transcutaneous electrical stimulation is considered a potential strategy to improve diaphragmatic strength in these patients, but there is currently a lack of evidence on this subject.
**Objectives:** The main objective of this study is to evaluate the safety of transcutaneous electrical phrenic nerve stimulation in sedated critically ill patients on invasive MV ventilation with continuous mandatory modes. The secondary objective is to assess the feasibility of this intervention in this type of patients.
**Methods:** Case series study in critically ill patients. After 12 h of invasive MV, critically ill sedated (RASS −4 to −5) adult patients received unilateral transcutaneous electrical phrenic nerve stimulation in the anterior cervical region. We used a Compex® Rehab Chattanooga Theta 4 Channel electrostimulation device with a motor point electrode to deliver up to 30 min per day of symmetrical bidirectional rectangular pulses. Electrostimulation parameters were as follows: frequency 8–10 Hz, pulse time 300 µs and intensity 0.5–12 mA. Safety was assessed by the measurement of alterations in hemodynamic (> 20% variation in heart rate and/or mean arterial pressure and occurrence of cardiac arrhythmias) and respiratory (5% decrease in oxygen pulse oximetry saturation) parameters. Feasibility was evaluated through the measurement of asynchrony index (not feasible if > 10%) and phrenic nerve stimulation success rate.
**Results:** A total of 28 patients (ages 65 ± 14) were stimulated and 67 sessions were performed (2.39 mean sessions per patient), with a diaphragmatic stimulation success rate of 73.1% (49 sessions). The mean time to locate the phrenic nerve was 6 min (interquartile range 13). The mean frequency and intensity achieved during electrostimulation were 8.04 ± 0.84 Hz and 2.24 ± 0.99 mA, respectively. One patient (1.5%) presented a mean arterial pressure variation of 20%, but no other safety events occurred among the other patients. There were no significant changes in asynchrony index (0% VS. 0%, $P < 0.001$).
**Conclusions:** This case series study in sedated critically ill patients on invasive MV suggest that transcutaneous electrical phrenic nerve stimulation is safe and feasible in this population of patients.

***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001235

**Introduction:** Cytoreductive surgery (CRS) and hyperthermic intraperitoneal chemotherapy (HIPEC) are treatments for peritoneal carcinomatosis in patients with digestive, ovarian, and primary peritoneal cancer. Often, regimens based on cisplatin and/or mitomycin are used. Hematologic toxicity secondary to these treatments is a poorly established complication due to the scarcity of studies, with results varying considerably, with percentages ranging from 2 to 38% (1,2,3). Cisplatin is a known antineoplastic agent for its myelosuppressive effect in systemic treatments, although its use in intrabdominal therapies may decrease the risk of toxicity by crossing in limited amounts into the systemic circulation (1,4). Identifying the frequency of these complications, associated factors, and understanding their impact during the postoperative period could be essential for implementing preventive strategies within post-surgical recovery protocols.
**Objectives:** Analyze whether there are differences in hematologic complications among patients admitted to the Intensive Care Unit (ICU) after undergoing cytoreduction and HIPEC, distinguishing between those treated with cisplatin-based hyperthermic intraperitoneal chemotherapy (HIPEC) and those who received mitomycin-based HIPEC.
**Methods: Design:** This is a prospective observational study in a Spanish polyvalent ICU of patients admitted after undergoing cytoreduction and HIPEC from January 2013 to December 2024. Recorded data included age, sex, cancer type, severity at ICU admission (APACHE II and SOFA scores), type of chemotherapy used, daily blood count and coagulation times, hemorrhagic complications, ICU mortality, and length of stay. We defined leukopenia as < 4000/µl, thrombocytopenia as < 150,000/µl, anemia as hemoglobin ≤ 10 g/dl, coagulopathy as INR ≥ 1.3 and/or APTT > 37 s, and hypofibrinogenemia as < 200 mg/dl.
**Analysis:** Quantitative variables are described with mean and standard deviation or with median and interquartile range using the U-Mann–Whitney test for analysis. For categorical variables, percentages were calculated and compared using Fisher's exact test. In all cases, $p < 0.05$ was considered statistically significant.
**Results:** A total of 123 patients were included, of whom 111 had haematologic alterations. 31 (49.2%) were males. The mean age was 59.32 ± 10.54 years. 104 (84.6%) had digestive cancer and 19 (15.4%) gynecological cancer. The mean APACHE II and SOFA scores at ICU admission were 8.5 (6–12) and 2 (1–3), respectively, with a Charlson index of 6, without statistically significant differences. It was observed that patients treated with cisplatin had a significantly higher positive fluid balance compared to those treated with mitomycin, with a statistically significant difference. There were no differences in the need for mechanical ventilation at admission, use of amines, and need for blood products. The mean ICU stay was 5 (4–5) days. ICU mortality was 0.8%, but it was not related to hematologic alterations or the presence of bleeding.

### Unconventional application of electrical impedance tomography in patients with significant thoracic deformities due to trauma

I. Minev[1]

[1]Anesthesiology, Emergency and Intensive Care Medicine, Medical University of Plovdiv, Plovdiv, Bulgaria

**Correspondence:** I. Minev

***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001237

**Introduction:** ARDS develops in 17% of the cases with isolated pulmonary contusion and in up to 78% of the cases with additional injury [1]. The risk is higher (82%) if the contusions exceed 20% of the lung volume [2]. The heterogeneity of the injured lung parenchyma results in inadequate gas flow distribution. It is crucial to optimize the respiratory monitoring in order to improve the protective mechanical ventilation [3]. The electrical impedance tomography (EIT) is used to evaluate lung mechanics [4] and support mechanical ventilation [5]. The informational value of the method is significantly reduced due to the lack of guidelines for reconstruction of personalized and reliable EIT images with sufficient spatial resolution.

**Objectives:** To increase the informational value of the EIT images taken at an unconventional level of interest.

**Methods:** A previously developed method for defining a level of interest, placement of EIT electrodes and personalized reconstruction of the EIT images [6], is applied in patients with thoracic trauma and monitored with EIT monitor PulmoVista 500 and Draeger EIT Data Analysis Tool 6.3. Anonymized raw data from the EIT monitor are used. To increase the informational value of the method, the number of the fem mesh elements is increased. A pixel size of 5 × 5 mm is accepted optimal—providing sufficient spatial resolution without significant increase in the computational time. The result is proportional 2D color-coded diagram representing the body composition based on water/gas content. The spatial conformity of the standard and personalized EIT images is analyzed.

**Results:** The application of the original method (Fig. 1) resulted in significant spatial conformity between the CT scan and the personalized EIT image taken at the corresponding thoracic level (Fig. 2). Due to the thoracic deformation, standard and personalized EIT images differ significantly. The altered chest and lung mechanics are not correctly represented on the standard EIT image, where a standardized contour of the "patient's" thorax and a blend present unreliable image with low spatial resolution that gives a very simplified idea of what and where it happens. Although the chest deformation suggests impaired ventilation in the ventral region of the right lung, on the standard EIT image (Fig. 3) the ventilation in this area is visualized better than in the dorsal region. The personalized reconstruction of the EIT image provides significant overlapping conformity, resulting in increased informational value concerning the spatial resolution of the images. The color coding of impedance distribution improves structural recognition and spatial evaluation of gas flow distribution, reflecting patient's anatomic characteristics.

**Conclusions:** The selected pixel size and the personalized reconstruction of the EIT images significantly optimize lung ventilation monitoring and increase the informational value of the EIT applied in patients with thoracic wall deformities due to trauma.

**Introduction:** Mediastinitis (MD) is a rare but severe and rapidly progressive infection of the mediastinum with different aetiologies. If not promptly treated is associated with high morbidity and mortality.
**Objectives:** To characterize a cohort of critically ill patients with MD.
**Methods:** This is a retrospective single-centre study of 38 patients with MD admitted to the ICU between 2018 and 2023 in a tertiary hospital in Portugal. Patient demographics, risk factors, causative pathogens, organ support, antimicrobial and surgical treatment and mortality were analysed. SPSS 27 as used for statistical analysis.
**Results:** In our series of 38 adults, 57.9% were female, with a median age of 62 y and 13.2% had cancer as comorbidity.
Median SAPS II and SOFA score on ICU admission were 31.00% and 3.0, respectively.
Descending necrotizing MD, 47.4%, was the most frequent aetiology followed by oesophageal perforation in 39.5% and post-surgical sternal wound infection in 10.5%.
Causative microorganisms were documented in 25 cases (65.8%) and 56.0% of them were polymicrobial. Gram-positive bacteria were the most frequent pathogens (80.0%) followed by Gram negative (40.0%) and anaerobes (32.0%). Fungi were present in 24.0% of all microbiologically documented MD and secondary bacteraemia was present in 20.0% of them.
Empirical combination of antimicrobials was used in 86.8% of the patients (an antifungal was included in 34.2% of them) and it was considered appropriate in 88.0% of all microbiologically documented cases. Empirical treatment was changed in 65.8% of the patients: 28.9% as stepdown therapy, 13.2% due to superinfection, 10.5% due to toxicity and in 7.9% due to inadequacy. Mean duration of antimicrobial treatment was 30.5 days and source control surgery was performed in 30 patients (78.9%). Invasive mechanical ventilation and vasopressors were used, respectively, in 73.4% and 68.4% of the cases. Tracheostomy was performed in 9 patients (23.7%). Median ICU length of stay (LOS) was 16 days. ICU, 28 days and hospital mortality were 10.5%, 13.2% and 21.1% respectively.
In univariate analysis, male gender ($p = 0.003$) and cancer as comorbidity ($p = 0.004$) were the only variables associated with hospital mortality. No independent risk factors for hospital mortality were found.
**Conclusions:** Although not very frequent, MD is associated with a heavy antimicrobials' consumption, need of multiple surgical interventions for source control and high use of ICU resources. Despite low mortality, it is associated with prolonged ICU LOS.

***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):** 001239

**Introduction:** Acute respiratory distress syndrome secondary to COVID-19 (C-ARDS) overcrowded the intensive care units (ICU) in the world with a high mortality rate. Mechanical ventilation (MV) remains the most important aspect of managing patients with ARDS; however, as it is a new pathology, the evidence of ventilatory variables associated with mortality is not entirely clear. In 2021, a new variable was described, which is superior to other ventilatory markers in ARDS due other pathologies, however, its possible usefulness in patients with C-ARDS has not been described.
**Objectives:** To assess linear power as a mortality risk marker in patients with C-ARDS in ICU.
**Methods:** After approval by the local research and ethics committees (HGL-CIS-2022/038), a retrospective cross-sectional analytical study was carried out in the intensive care unit of the Leon General Hospital in the period July 2021 to February 2022; all records of patients of both genres over 18 years old with a diagnosis of ARDS according to the Berlin definition with IMV and a positive test for COVID-19 (PCR or antigen) were included. Pregnant patients, MV in spontaneous modes or non-conventional modes, with known chronic disease (COPD, pulmonary fibrosis, interstitial diseases, etc.).
The present study adhered to ethical standards on health research, the Helsinki declaration and the Strobe declaration. It was a sampling of consecutive cases, and a total sample size of 80 patients was calculated, expecting a linear power difference between those who died and those who survived of at least 20%, a confidence of 95% and a power of 80%.
The study was divided into two groups: patients who died and patients who were discharged from ICU. To the entire population, linear power at admission to the ICU was calculated with the following formula:
Linear Power = (4 × driving pressure) + respiratory rate.
**Results:** We included 60 patients who met all selection criteria for this study during this specified period. 58.3% of the patients were of the male gender, with an average (± SD) of 52 years (± 14.3 years) and an average BMI of 30 kg/m$^2$ (± 5.3 kg/m2); in 83.3%, the ventilatory mode was control volume with a median interquantile range (IQR) of 5.1 ml/kg (4.5–5.9 ml/kg), PEEP of 8 cmH2O (7.75–10 cmH2O), FiO2 of 0.9 (0.6–1) and 90% of the patients were in prone position; the ventilatory monitoring variables, ΔP 15 cmH2O (12.7–17 cmH2O), MP of 20.8 J/min (17–24.3 J/min) and linear power of 82 (72–93.7); finally, mortality was 43.3% (Table 1).

In the study, it was divided into 26 patients in the death group and 34 patients in the group who was discharged from ICU. When comparing both groups, only gender ($p=0.043$) and weight (84.7 vs 79 kg, $p=0.04$) had a difference in demographic variables; in ventilatory variables, PEEP (10 vs 8 cmH2O, $p=0.017$), MP (23 vs. 18 J/min, $p=0.035$) and ΔP (16 vs 14 cmH2O, $p=0.021$) were higher in patients who died, and 53% of the death group had a ΔP upper than 15 cmH2O ($p=0.056$, RM 2.8 IC at 95% 0.96–8.13) and 67% a MP greater than 17 J/min ($P=0.006$, RM 3.22 95% IC 1.5–13) (Table 1).

The linear power in the death group was 89.5 (77–103.2), and in the discharge group, it was 78 (71.25–88, $p=0.031$); in the ROC curve analysis, the linear power had an AUC of 0.663 (0.525–0.802, $p=0.031$, Figure 1) with mortality. When divided into quartiles, the second quartile was the one that presented the best prognostic capacity (sensitivity of 73% and specificity of 60%, Table 2) and increased the probability of risk (OR 3.5, 95% CI 1.13–12.3,) of die; Likewise, those with a linear power greater than 80 had lower survival compared to the group less than 80 (log rank test, $p=0.043$, Figure 2).

In the multivariable regression analysis, male gender (OR 4.63, 1.16–14.23) and linear power (OR 4.4, 95% CI 1.15–17.3) were the risk factors associated with mortality.

**Conclusions:** Linear power greater than 80 is a possible mortality risk variable in C-ARDS patients with IMV in ICU.

**Table 1 (abstract 001239)** General data of the population and comparison between the death group and the intensive care discharge group

| | N=60 | Death n=26 | Discharge n=34 | p |
|---|---|---|---|---|
| Male, n (%) | 35 (58.3) | 19 (73.1) | 16 (47.1) | **0.043** |
| Female, n (%) | 25 (41.6) | 7 (27) | 18 (53) | **0.043** |
| Age, years | 52 (± 14.3) | 54.5 (± 11.3) | 50.6 (±16.3) | 0.305 |
| Weight, Kg | 80 (±15.2) | 84.9 (±16.23) | 77 (±13.5) | **0.045** |
| BMI, Kg/m2 | 30 (±5.3) | 29 (26-33) | 30 (26-34) | 0.952 |
| Prone position, n (%) | 54 (90) | 26 (100) | 28 (84) | **0.025** |
| Tidal volume, ml/kg* | 5.1 (4.5-5.9) | 5.05 (4.3-5.7) | 5.2 (4.74-6) | 0.483 |
| PEEP, cmH2O | 8 (7.75-10) | 10 (8-10.75) | 8 (7-10) | **0.017** |
| Respiratory rate, fr/min | 26 (22.8-28) | 26 (23.5-28) | 26 (22.5-28) | 0.712 |
| FIO2, decimals* | 0.9 (0.6-1) | 0.95 (0.81-1) | 0.85 (0.5-1) | 0.137 |
| Plateau pressure, cmH2O | 23.5 (21-26) | 25 (22-27.8) | 23 (20-25) | 0.069 |
| Static compliance, cmH2O | 27(22-37) | 28.8 (22.8-37) | 26.6 (22-36) | 0.737 |
| Driving pressure, cmH2O | 15 (12.7-17) | 16 (14-19) | 14 (12-16) | **0.021** |
| Mechanical power, J/min | 20 (17-24) | 23 (19-25) | 18 (14-23) | **0.035** |
| Linear Power | 82 (72-93.7) | 89.5 (77-103.2) | 78 (71.25-88) | **0.031** |
| Pao2, mmhg | 75 (66-91) | 74.5 (66.25-86) | 76 (67.25-91) | 0.676 |
| Paco2, mmhg | 50 (42-67.7) | 59 (42.25-79.25) | 48 (42.1-61) | 0.192 |

It is described as mean (±SD), median (q1-q3), number (n), percentage (%), BMI (body mass index), PEEP (positive end-expiratory pressure), FiO2 (inspired fraction of oxygen in units), PaO2 (blood pressure of oxygen), PaCO2 (blood pressure of carbon dioxide), millimeters of mercury (mmhg).

**Table 2 (abstract 001239)** Division of linear power into quartiles

| Quartil Linear power | | OR (IC al 95%) | Sensitivity | Specificity |
|---|---|---|---|---|
| First quartile (1Q) | 73 | 4.1 (0.8-21) | 92% | 26% |
| Secondquartile (2Q) | 80 | 3.5 (1.13-14) | 75% | 60% |
| Thirdquartile (3Q) | 94 | 3.1 (1.06-10) | 46% | 79% |

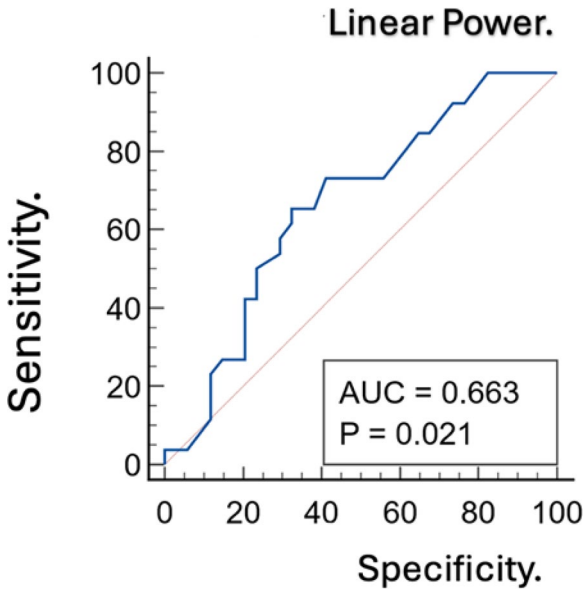

**Fig. 1 (abstract 001239)** ROC curve with area under the linear power curve of 0.663 (IC al 95% de 0.530–0.780, $p=.021$)

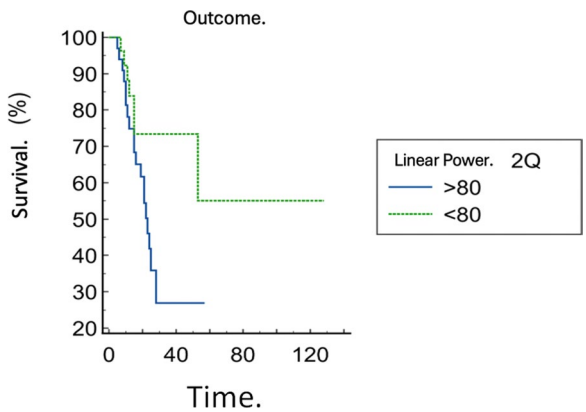

**Fig. 2 (abstract 001239)** Kaplan Meier survival curve, with a comparison of the curves by Log-rank test (x2 4.083, $p=0.043$)

**Introduction:** Contrast encephalopathy is a rare and potentially serious entity that affects patients undergoing angiographic procedures with iodinated contrast. It involves an alteration of the blood–brain barrier and different clinical symptoms of the nervous central system.
**Objectives:** To describe the characteristics and evolution of patients with a clinical profile compatible with contrast encephalopathy after a cerebral aneurysm embolization.
**Methods:** This is a retrospective descriptive study of patients admitted to our Intensive Care Unit (ICU) in 2023, with a diagnosis of contrast encephalopathy after a cerebral angiographic procedure. We evaluate the clinical setting, radiological alterations, treatment, and evolution of those patients.
**Results:** Four female patients aged between 45 to 65 years were admitted to our ICU requiring a cerebral angiography, and in three cases, the diagnosis was a cerebral aneurysm. Low osmolarity iodinated contrast (300 mg/ml) was used in angiography. Three of the patients were smokers, and none had impaired renal function. After the procedure hemiparesis was observed in two patients, seizures in another two, dysarthria in one case, blindness and diabetes insipidus were associated with one of the above. Two brain MRI were performed that ruled out acute ischemic lesions and intracranial bleeding, and two brain CT angiograms described hemispheric cerebral edema with asymmetry in vascularization in one patient. Three patients received treatment with corticosteroids. Within 72 h, all four patients showed clinical improvement.
**Conclusions:** Cases of contrast-induced encephalopathy are rare after the use of endovascular iodinated contrast agents. The literature has included this complication associated with cardiac catheterizations for years and currently cases after cerebral angiograms are published more frequently. Patients who have received high doses of contrast directly into cranial vessels are at greater risk. The physiology is still unknown, but the literature describes osmotic damage to the blood–brain barrier due to direct toxicity of the contrast on the brain tissue in combination with the effects of its osmolarity. Despite the use of hypoosmolar contrasts, these alterations may exist. Patients with no clinical history nor previous brain pathology may suffer from this pathology. The neurological alteration ranges from visual impairment, language impairment and motor alteration to seizures and coma. Imaging tests performed when clinical worsening occurs usually describes few alterations, although cerebral edema is common. A clinical-radiological improvement is described in the first days in most patients, but sometimes the affection is more serious and persists over time. Treatment with corticosteroids continues to be a therapeutical option. We must think about this entity that appears more often than

we suspect, after a clinical deterioration of those patients who underwent procedures with iodinated contrast, always ruling out other complications, to apply a treatment for promptly recovery.

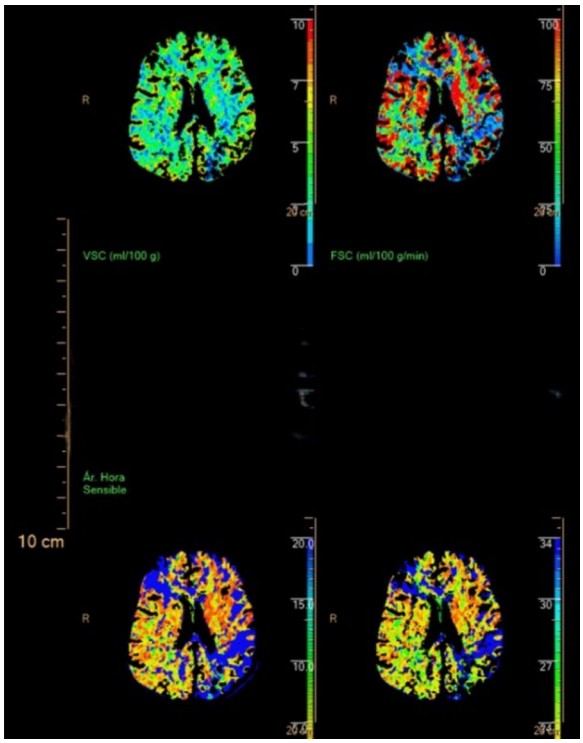

**Fig. (abstract 001242)** Asymmetry in perfusion maps with increase in time and slight decrease in flow in the territory of the right MCA

**Introduction:** Status epilepticus (SE) has been defined as the clinical condition that results from the failure of mechanisms that control the onset or termination of seizures, causing an abnormally prolonged epileptic state. This form of epilepsy presents considerable incidence in general population (40/100.000) and associated high hospital mortality (9–52%) and morbidity, with long-term severe neurological impairment (severe neurological status in 39% of survivors at 90 days). According to this, quick control of SE is crucial, being benzodiazepines and antiepileptic drugs the first- and second-line recommended treatments. When we fail to control status epilepticus, we refer to it as refractory status epilepticus (RSE). This condition obligates physicians to start sedation. If, although deep sedation, RSE is not controlled, we define it as super-refractory status epilepticus (SRSE). This other form of epilepsy is a maximum severity disease with high ratios of neuronal morbidity and mortality. Conventional sedative drugs usually fail to subdue SRSE, therefore, considering alternative drugs such as isoflurane may be an option.
**Objectives:** To assess the efficacy and safety of inhaled isoflurane in the ICU for the management of super-refractory status epilepticus (SRSE).
**Methods:** This is a retrospective review of 6 cases of SRSE treated with inhaled isoflurane in the ICU (using the AnaConDa-S device) due to the ineffectiveness of conventional sedative and anticonvulsant drugs. Control of seizures was considered as absence of clinical and/or electroencephalographic seizures after the initiation of isoflurane, with no recurrence after withdrawal of the drug. In addition, variables such as mortality, functional outcome at ICU discharge, and occurrence of complications attributable to isoflurane were assessed. Because of previous reports of alterations in the T2 pattern of nuclear magnetic resonance (NMR) imaging, we studied the occurrence of these lesions in our patients.
**Results:** Control of SRSE was achieved in 4 of 6 patients following initiation of isoflurane treatment. 4 of the 6 patients died from serious concurrent pathologies, with SRSE controlled in 3 of the 4 deceased patients. 2 of the deaths were attributed to uncontrolled SRSE (mortality of SRSE in different series varies between 20 and 50%). The 2 surviving patients with controlled SRSE were discharged from the ICU at their baseline functional status. All cases required vasopressors during isoflurane treatment at a dosage similar to that required during the use of other sedatives. 1 patient developed ventilator-associated pneumonia 48 h after starting isoflurane, with no clear causal relationship established. No other adverse effects were observed. MRI studies were conducted in 5 of 6 patients, with only 3 of them performed after the use of isoflurane. None of the 3 cases showed new lesions attributable to the drug.
**Conclusions:** Isoflurane seems to be an effective rescue treatment for controlling SRSE. Patients showed hemodynamic alterations requiring vasopressors without other apparent complications related to isoflurane use. These data suggest that isoflurane could be considered as a safe and effective alternative in the management of SRSE.

**Introduction:** Recent evidence has confirmed the usefulness and reliability of ultrasound (US) localization of the central vein catheter (CVC) tip, potentially altering clinical practice behavior in recent years. However, no previous study has investigated common clinical practice behavior. Thus, the World Interactive Network Focused On Critical UltraSound (WINFOCUS) launched an international worldwide audit of CVC confirmation practices among its members.
**Objectives:** This survey aims to delineate global practices regarding CVC placement confirmation, with a particular emphasis on the utilization of US. The findings from this survey will also guide the design and implementation of a multinational prospective observational study investigating the use and outcomes associated with CVC placement.
**Methods:** Between April 4th and September 9th, 2023, a web-based cross-sectional survey was distributed through the WINFOCUS World Ultrasound Network across five continents. The survey was individually emailed to members of the WINFOCUS mailing list using the SurveyMonkey online platform. A cover letter attached to the email briefly explained the study and provided a link to the online survey. Two reminders were subsequently sent to encourage participation. Descriptive statistics were utilized to summarize the data. Results for continuous variables were expressed as median ± IQR (Interquartile Range). Qualitative items were compared using a Chi-square test, with a p-value < 0.05 considered statistically significant. Data analysis was performed using SPSS version 27.0.
**Results:** One thousand, two hundred and forty-six forms were submitted to the online data platform. All data were included in the final analysis. The survey reached 1246 practitioners, and of these, 1227 (98.5%) agreed to participate and responded to the survey. The continents of respondents were: Europe (33.5%), Asia (28.3%), South America (25.6%), Africa (5.8%), North America (5.3%), and Oceania (1.5%). A 92.2% of respondents reported inserting CVCs, mainly physicians (95.4%), specializing in critical care medicine (27%), anesthesiology (22%), and emergency medicine (14.3%). Over half had > 6 years of practice (51.8%) and placed > 200 central lines, often under US guidance (70%). To confirm CVC placement, CXR was "always" used (52%), followed by US wire visualization (45%). Other methods included saline/fluid injection (23%), blood tracking (22%), intravascular ECG (8%), blood gas analysis (6%), and ultrasound contrast injection (4%). Among those using US, methods included contrast medium injection with TTE/TEE (8.2%), TTE apical view (7.3%), TTE bicaval subcostal view (6.4%), and TEE (2.6%). 9% used no contrast, 34% used saline, and 57% used air-blood-saline or contrast mixtures. Obstacles to using US included institutional guidelines (33.9%), medico-legal concerns (13.8%), and lack of US skills (8.8%).
**Conclusions:** Although current scientific evidence supports the use of ultrasound (US) for confirming the position of CVCs, many physicians still do not fully utilize US and incorrectly regard chest X-ray (CXR) as the standard for checking tip position. We believe that US should be the primary method for confirming catheter malposition, with CXR reserved for specific situations where US is not feasible. To enhance patient safety, optimize hospital resources, and minimize radiation exposure, we advocate for a de-implementation strategy to discourage the systematic use of CXR for checking CVC positioning.

**Introduction:** The recommendation for using baclofen in alcohol withdrawal makes this drug more accessible and provides an opportunity for voluntary intoxication by the patient or its surrounding.
**Objectives:** Describe the epidemiological, clinical and prognostic characteristics of acute intoxications with baclofen admitted to the intensive care unit.
**Methods:** This was a retrospective descriptive study conducted in a toxicology Intensive Care Unit over a period of 4 years (2020–2023). We included patients admitted to the ICU for baclofen intoxication. Patients with polydrug intoxication were excluded.
**Results:** Forty-one patients were included. The average age was 28 ± 13 years. Ten patients (25%) were children. The gender ratio was 0.46. The mean IGS II and APACHE II scores were 28 ± 11 and 10 ± 4, respectively. Twelve patients (30%) had psychiatric history. All cases were suicidal acts. Intoxication was associated with alcohol consumption in 5 patients with an average blood alcohol level of 1.7 g/L. The average time to consultation was 6 ± 3 h. The average presumed ingested dose was 420 ± 320 mg. Fourteen patients (34%) experienced agitation episodes. Six patients (14.6%) had tonic–clonic seizures. The mean GCS score at admission was 8 ± 4. Toxic coma was the main reason for mechanical ventilation, required in 34 patients (83%). High presumed ingested dose was associated with a risk of requiring orotracheal intubation (170 ± 70 vs. 320 ± 66, $p = 0.005$). Eighteen patients developed aspiration pneumonia. Three patients had ventilator-acquired pneumonia during ICU stay. The average duration of mechanical ventilation was 48 ± 32 h. Electrocardiographic abnormalities included atrioventricular block ($n = 4$, 10%) and prolonged QT interval ($n = 3$, 7%). The average hospitalization duration was 3.5 ± 2 days. All patients survived.
**Conclusions:** Signs of baclofen intoxication are mainly neurological. The prognosis is favorable when management is adequate.

**Topic:** Poisoning/Toxicology/Pharmacology

### Can we optimize blood pressure targets by monitoring cerebral autoregulation before revascularization in endovascular therapy for acute ischemic stroke?

A. Krönlein[1], C. Amar[2], R. Vithal[1], A. El-Mehri[1], P. Martner[2], L. Block[1], H. Odenstedt Herges[1], J. Liljencrantz[1]

***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001247

**Introduction:** Typically, 1.9 million neurons are lost each minute in which ischemic stroke is untreated (1). Endovascular therapy (EVT) significantly improves outcomes in acute ischemic stroke (AIS) (2). Loss of cerebral autoregulation makes AIS patients vulnerable to variations in blood pressure. However, the ideal blood pressure for individual patients before and after revascularization remains unclear (3,4). Before revascularization, blood pressure targets guided by the cerebral autoregulation status holds the potential to save penumbra.
**Objectives:** To investigate the feasibility of determining optimal blood pressure from cerebral autoregulation status before revascularization during EVT.
**Methods:** In this prospective observational study, we have completed the data collection from 25 AIS patients undergoing EVT under general anesthesia. Mean arterial blood pressure (MAP) and regional brain tissue oxygenation using near-infrared spectroscopy (NIRS; INVOS with rSO2) as a surrogate measure of cerebral blood flow were continuously recorded. Changes in rSO2 in response to variations in MAP were recorded and averaged over 10 s periods. The ICM + software package (ICM + ®, Cambridge Enterprise, University of Cambridge, UK) was used for time-correlation analysis to calculate tissue oxygenation derived autoregulatory index (TOx) which can be used to identify the MAP-range at which the autoregulation function was best preserved3. Figure 1 shows the parabolic curve of MAP fitted to TOx in which the nadir of the curve corresponds to the optimal MAP (based on autoregulatory function) for each individual patient. The calculated optimal MAP was compared to the patient's initial blood pressure levels upon presentation.
**Results:** So far, a subset of 6 patients have been analyzed. In 5 out of the 6 patients, a tissue oxygenation derived autoregulatory index could be calculated despite short registration times before revascularization was achieved (15 min on average). In these patients, the range of optimal blood pressure was 100–115 mmHg which correlated ($r = 0.9$) to the spontaneous achieved pre-procedural levels ranging from 85 to 117 mmHg.
**Conclusions:** Calculating cerebral autoregulation indices before revascularization in AIS patients appears feasible despite the short data registration period. Optimal blood pressure levels correlated closely with pre-procedural levels, emphasizing the importance of meticulous blood pressure control during EVT patient management. Analyses of the full data set awaits.

### Clinicians insights on do not resuscitate and care escalation decisions: understanding the barriers and improving practices

K. Archer[1], F. Quinn[1], J. Gwyn[2]
[1]Intensive Care Medicine, Birmingham Heartlands Hospital, Birmingham, United Kingdom; [2]Intensive Care Medicine, Good Hope Hospital, Birmingham, United Kingdom
**Correspondence:** K. Archer
***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001248

**Introduction:** In the UK, the ReSPECT (Recommended Summary Plan for Emergency Care and Treatment) form is used to document whether a patient is for resuscitation in the event of cardiorespiratory arrest, and what levels of escalation are appropriate should they become critically unwell [1]. This includes stating that a patient is for resuscitation and for escalation to treatment on ICU. Usually, these forms are easily completed, but decisions about resuscitation and escalation of treatment are often made out of hours and at a late stage during a patient's hospital journey. This can cause delays in management, increase workload for out of hours teams, tension between intensive care and medical staff, and harm to patients.

**Objectives:** To understand clinicians' knowledge of ReSPECT forms, escalation decisions, and when they are using these. We wanted to see if there are barriers to use and what these are. We can then use these results to guide the development of educational events and resources to improve clinicians' use of ReSPECT forms and decision-making surrounding escalation of treatment, which should improve patient care.
**Methods:** We created a survey using Google Forms, which was circulated to consultants and registrars working across two hospital sites. It was distributed to medical, surgical, and emergency department doctors via e-mail and WhatsApp groups. Information was collected anonymously.
**Results:** We received 33 responses. Most respondents were medical consultants. 78.8% said they felt comfortable making resuscitation and escalation decisions 80–100% of the time. It was felt that the most appropriate time to make these decisions was on admission or at the request of a patient or family. Only 24.2% of respondents said they would complete a form if the patient was for resuscitation and full escalation of treatment. The most common reasons for not making these decisions were time constraints and fear of offending the patient or relatives. However, 93.8% felt legally and professionally supported to make these decisions. Although 75.8% of respondents felt they receive sufficient training on these issues, 57.6% were interested in attending refresher courses.

**Conclusions:** Our survey shows that senior medical clinicians across our two hospitals feel able to make resuscitation and escalation of treatment decisions. Documentation around these issues appears to only occur if a patient is not suitable for resuscitation and has limitations to their treatment options. These conversations and decisions are time consuming and this impacts on the ability of busy clinicians to perform these tasks. Despite feeling supported to make these decisions, a significant number of clinicians felt a refresher course would be beneficial. We are looking to develop an educational event aimed at discussing these topics and to develop inter-speciality associations. Having prompts on our electronic patient system would remind clinicians to discuss these topics, as well as incorporating it as part of the ward round checklist.

***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001249

**Introduction:** Patient handover is the main activity which take place in the ICU and is based on and effective communication between healthcare professionals and it means a high risk activity of which adverse events derive.
**Objectives:** To implement a protocol in our ICU for carrying out a multidisciplinary and standardized structured patient handover focused in the handover of diary objectives from each patient.
To get the achievement of the quality indicators proposed by European Society of Intensive Care Unit (ESICM) and the Spanish Society of Intensive Care Unit (SEMICYUC).
**Methods:** A Medical patient handover with "Organs and System" structured information was established followed by a multidisciplinary round with nurses, nursing auxiliaries and porters using a checklist. The protocol was established during 6 months like a monitoring period. At the end of this period, ESICM quality indicators were calculated, adverse events were analyzed, and a survey was filled by the healthcare professionals.
**Results:** Quality process indicator "Standardized Handover procedure for discharging patients" obtained was 85% (ESICM consensus 100%, SEMICYUC standard 90%). Quality indicator "Presence of routine multidisciplinary clinical ward rounds" obtained was 70% (ESICM consensus 100%, SEMICYUC standard 80%). About the survey filled by Healthcare professional, 8 physicians were asked, 87% considered the protocol was useful, 75% considered it was easy to carry out and as difficulties they found lack of coordination between the time of the patient handover, the time for bathing patients and the time of the multidisciplinary round. 20 nurses were surveyed, 90% considered the protocol was useful, 80% considered it was easy to carry out and as difficulties they found lack of coordination between the time of the patient handover, the time for bathing patients and the multidisciplinary round resulting in a delay in the daily tasks. Finally, 15 nursing auxiliaries were surveyed, 86.67% considered the protocol was useful, 86.67% considered it was easy to carry out and they found the same difficulties as nursery. About adverse events, no adverse events derived from patient handover were found, and there were no differences between the number of events out of the monitoring period.
**Conclusions:** To implement a protocol in an ICU, carrying out a multidisciplinary and standardized structured patient handover is possible, which decreases adverse events derived from patient handover.
- A longer period of establishment is necessary for getting the standard of quality indicators.
- Checklist use makes easier the transmission of the information about patient diary objectives.

### Relationship between perceived stress, perceived social support and family satisfaction among relatives of adult critical patients: a cross-sectional study

V. Nilo[1], N. Rojas[1], C. Padilla-Fortunatti[1]
[1]School of Nursing, Campus San Joaquín, Pontificia Universidad Catolica de Chile, Macul, Chile
**Correspondence:** V. Nilo
***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001250

**Introduction:** Admission to the intensive care unit (ICU) is a difficult and stressful situation for patients and relatives. Several stressors for ICU relatives are described such as uncertainty, communication issues, changes in roles and responsibilities, and decision-making difficulties (1). The stressful ICU environment can affect the way relatives evaluate their satisfaction with the quality of ICU care (2,3). In this scenario, perceived social support may serve as a stress buffer for ICU relatives (4,5). However, evidence of the influence of perceived stress and perceived social support on family satisfaction is limited.
**Objectives:** To explore the relationship between perceived stress, social support, and family satisfaction in relatives of ICU patients.
**Methods:** A correlational cross-sectional study was conducted in a private health clinic in the central region of Chile. Relatives of ICU patients with > 48 h of stay were eligible and completed the perceived

stress scale (PSS), the Medical Outcomes Study Social Support Survey (MOS-SSS), and the Family Satisfaction with Care in the Intensive Care Unit-24 (FS ICU-24). Sociodemographic and patient clinical data were also collected. Data were analyzed using descriptive statistics and Spearman rho correlations to explore potential associations between the PSS, MOS-SSS, and FS ICU-24 (overall satisfaction, satisfaction with patient and family care, satisfaction with communication, and satisfaction with decision-making). The study was approved by two Ethics Committees (ID: 220922006 and 061404-23).

**Results:** A convenience sample of 50 relatives were enrolled with 70% being female and a mean age of 50.1 years (*SD* = 15.5). Mean scores for perceived stress, perceived social support, and family satisfaction levels were 19.3 (*SD* = 7.9), 92 (SD = 17.7), and 75.6 (*SD* = 15.), respectively. Concerning FS ICU-24 dimensions, the mean scores were 75.8 (*SD* = 15.1) for satisfaction with patient and family care, 76.3 (*SD* = 20.53) for satisfaction with communication, and 73 (*SD* = 25.2) for satisfaction with decision-making. Then, perceived stress was negatively associated with overall satisfaction ($r = -0.384$, $p = 0.006$), satisfaction with patient and family care ($r = -0.359$, $p = 0.011$), satisfaction with communication ($r = -0334$, $p = 0.018$), and satisfaction with decision-making ($r = -0.338$, $p = 0.041$). Perceived social support was not statistically associated with perceived stress and family satisfaction.

**Conclusions:** Findings from this study increase knowledge regarding the negative impact of perceived stress on family satisfaction. Further studies are required to explore the possible influence of perceived social support on the relatives' ICU experience. Knowing the factors that influence family satisfaction may assist healthcare providers in improving family-centered care in the ICU.

### Correlation between gastric residual volume using ultrasound and manual aspiration for gastric reserve volume estimation in patients with enteral feeding intolerance

E. Hernandez-Dominguez[1], J. Garduño-López[1], M. A. Amezcua-Gutiérrez[1], J. C. Gasca-Aldama[1], S. I. Alba Cuevas[1], N. M. Sánchez Parada[1], F. Ordóñez Hernández[1], C. E. Lopez-Rodriguez[1], M. A. Juan Gomez[1], J. E. Castrejón Sánchez[1], N. L. Novoa Santander[1], M. A. Duran-Villa[2]

***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001251

**Introduction:** Enteral feeding intolerance continues to be a limiting factor in many patients in intensive care unit (UCI), which has generated the search for strategies that allow early detection, as well as the standardization of the evaluation of gastric functions with an examination of the abdomen at the patient's bedside. Traditionally, measurement of gastric residual volume by manual aspiration has been used as a method to monitor enteral feeding intolerance. In the search to improve safety and minimize complications in critically ill patients, determination of gastric residual volume by ultrasound could be a tool that allows the early diagnosis of enteral intolerance due to its high sensitivity and specificity to detect or rule out a full stomach in clinical scenarios in which the presence of gastric contents is uncertain. In addition to being highly reproducible, it can determine its correlation with gastric residual volume by manual aspiration, and it could also improve early detection in our unit and implement routine monitoring and treatment strategies that will benefit the patients.

**Objectives:** To correlate gastric residual volume measured by ultrasound and manual aspiration for gastric reserve volume estimation in patients with enteral feeding intolerance.

**Methods:** This is a descriptive, longitudinal, prospective study in patients admitted to the adult UCI of a tertiary hospital in Mexico City and in whom enteral feeding intolerance was documented their stay. We measured gastric residual volume using ultrasound and compared this measurement with manual aspiration for gastric reserve volume estimation.

**Results:**

We included 23 participants, and 59 measurements of gastric residual volume were performed using ultrasound and then compared with manual aspiration for gastric reserve volume. Parametric tests of normality were carried out with Kolmogorov–Smirnov with normal distribution. Of the 23 participants, 52% men, 47% women, and all participants were fed with a nasogastric tube. The mean age of the included participants was 48 years, mean BMI 28.4 kg/m2. The admission etiology was pneumonia 56.5% (N13), followed by cerebral vascular disease 26.1% (N6). The main comorbidities were obesity 34% (N8), systemic arterial hypertension 34% (N8), and diabetes 21.79% (N5).

A total of 59 measurements were made, estimating an average of 636 ml for gastric volume in 24 h using USG in contrast to an average of 634 ml for gastric volume obtained by manual aspiration, without identifying alterations in intra-abdominal pressure. Even in patients with greater residual, an average of 7.76 mmHg was found. Using the Pearson test, it was determined that there is a directly proportional correlation with a correlation coefficient of 0.97, and a significant $p < 0.01$.

The main clinical data associated with enteral intolerance were diarrhea in 26.08% (N6) of the participants, followed by vomiting and abdominal pain in 4.34% (N1) of the participants.

| | N (59) | Media (DE) | IC 95% |
|---|---|---|---|
| GRV USG 1* | 23 | 288 (13.08) | (260–317) |
| GRV USG 2* | 23 | 248 (13.11) | (219–277) |
| GRV USG 3* | 13 | 193 (19.47) | (151–235) |
| GRV USG 24 h * | 59 | 636 (168.70) | (563–638) |
| GRV 1* | 23 | 294 (13.97) | (263–324) |
| GRV 2* | 23 | 252 (19.57) | (210–295) |
| GRV 3* | 13 | 186 (20.00) | (143–230) |
| GRV 24 h* | 59 | 634 (176.93) | (557–710) |

* $p < 0.0001$, GRV USG (gastric residual volume by ultrasound), GRV (gastric residual volume by manual aspiration

**Conclusions:** The measurement of gastric residual volume by ultrasound is a reliable method to detect enteral intolerance early, with a high correlation and statistical significance. This represents benefits for the critically ill patient, since ultrasound at the point of care presents a strategy of cutting-edge, non-invasive that can be performed at the patient's bedside.

**Introduction:** Critically ill patients in the intensive care unit (ICU) often face serious infections and poor outcomes (1, 2). Their altered pharmacokinetics (PK) make antibiotic dosing challenging (3, 4). Achieving therapeutic antibiotic exposures may be improved with the use of model-informed precision dosing (MIPD) programs. This approach further individualises dosing and is a key advantage over a traditional therapeutic drug monitoring approach, in that, it can be performed prior to steady state, allowing for earlier dosing adjustment to attain target exposures (5). External evaluation of MIDP programs is essential to assess how well they perform in real-world clinical scenarios.
**Objectives:** To quantify and compare both a priori and a posteriori predictive performance of an antibiotic MIPD program in a heterogenous cohort of critically ill adults with infection.
**Methods:** The MIDP program, ID-ODS TM, was used to predict a priori and a posteriori concentrations for piperacillin, meropenem, cefepime, flucloxacillin and vancomycin using clinical and demographic data derived from a previous study in critically ill adults (GUIDE trial). Predicted concentrations were compared to observed concentrations using pre-specified acceptance criteria. Furthermore, the impact of predictions on theoretical dosing recommendations to achieve predefined drug exposures was assessed.

**Results:** One hundred and six patients were included in the external evaluation (see Table 1). The a priori predictive performance in 81 patients administered beta-lactams did not meet any pre-specified acceptance criteria. However, all beta-lactams met accuracy acceptance criteria for the a posteriori approach, although only cefepime demonstrated accep Table precision and F20 and F30 acceptance. In 25 patients administered vancomycin, a priori predictive performance met all acceptance criteria for accuracy and precision (see Tables 2 and 3). When assessing a priori theoretical dosing recommendation concordance, approximately 1 in 3 predictions led to an unnecessary dosing action. Concordance was similar with an a posteriori approach; however, overprediction was observed in 20% of meropenem predictions.
**Conclusions:** In a heterogenous adult ICU population, the a priori predictive performance of vancomycin was shown to be accep Table. Conversely, the a priori predictive performance for the beta-lactams was not acceptable. Although predictive performance improved with the a posteriori approach for beta-lactams, only cefepime met acceptance criteria.

***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001255

**Introduction:** The intensive care unit can be a dangerous environment for the eyes (1). Ophthalmological complications are frequently encountered in ICU patients; ocular care is often overlooked as management focuses on organ failures (1,2). The most common eye problems are keratopathy (3.6%–60%), chemosis (9%–80%), and microbial keratitis (2,3). Currently, there are still patients with fluid overload in a significant percentage (4), and it has been proposed that chemosis could result in an objective sign for early identification.

**Objectives:** Evaluate the association of the degrees of chemosis with the daily accumulated fluid balance and determine if the Godet's sign is related to the degree of chemosis.

**Methods:** This is a trial analytical, observational, correlational, prospective, and longitudinal study. This study included adult patients over 18 years of age, who were admitted to the ICU. The filling out of nursing sheets was used as a tool, where daily fluid balances, uresis and other variables per hour are specified; finally, they were collected in a database in the period from July 1, 2022, to July 1, 2023. According to Will Jaffe et al. 2018, where they found an incidence of 80% of accumulated positive balance with mortality after 72 h with a p 0.05, the G*Power statistical program was used to know the sample size, using a size of the effect of 0.7, alpha error of 0.05 and statistical power of 0.80. Since it was an association study, the formula of events per variable was used, 10 x (number of variables/frequency of the outcome), resulting in a total of 218 patients, who met the outcome; 15% losses were calculated. Adding in the end, a total of 251 patients meet the outcome.

**Results:** The degree of chemosis was evaluated with the accumulated fluid balance, relating the milliliters of the balance to the degree of chemosis and the relationship with Godet´s sign, finding that patients who present chemosis (grade 2 and 3) have a risk of up to 2.3 times of having a balance of 8000 ml, but up to 3.7 times of having it more than 8000 ml, as well as 2.5 times of having Godet's sign+++ and 4.4 times of having Godet's++++, representing a strong association. A second adjusted multivariate analysis (aOR) was performed, again finding significance of the variables, with age being an adjusted OR 2.1 (95% CI 3.04–7.51, p 0.011), fluid balance < 8000 ml adjusted OR 3.3 (95% CI) 2.1–7.02, p 0.004), > 8001 obtained an adjusted OR of 5.6 (95% CI 1.98–4.21, p 0.010), Godet's sign 6 mm (+++) obtained an adjusted OR of 4.3 (95% CI 5.17–9.34, p 0.009), Godet 8 mm (++++) obtained adjusted OR of 6.1 (95% CI 8.11–12.4, p 0.025).

**Table 1 (abstract 001255)** Chemosis severity

| | |
|---|---|
| **Grade 0** | **Absent** |

| Grade 2 | Conjunctival edema with formation of depressions or "dellen" |
| Grade 3 | Conjunctival edema with prolapse through the eyelid aperture |

The adverse effects associated with fluid overload in critically ill patients are one of the major problems in ICU and have gained great relevance both in research and in obtaining practical ways to identify it; ultrasound-based protocols have recently been suggested (5,6). Trying to find an answer to the question: Where is the liquid? Is in the intravascular space or in the interstitial space? Our study addressed this question from a clinical point of view and demonstrated that patients with grade II chemosis had accumulated balances of at least 8000 ml and patients with grade III chemosis exceeded this. Currently, there is no study in critically ill patients that compares the relationship between chemosis and fluid balances, the result is innovative since it proposes to return to the clinical bases: jugular engorgement, Godet's sign and chemosis. Considering that it is also an easily reproducible method—available to everyone—that has not cost, no learning curve is required for its evaluation.

**Conclusions:** Patient inspection is the pillar of examination, but in the face of overwhelming technological change, it has been delegated by new generations. With this study, it becomes evident that returning to good foundations is essential in our practice, that there is no doubt that detecting chemosis will be of great help to limit the administration of fluids and/or decide strategies to eliminate excess cumulative.

**Introduction:** Gastrointestinal (GI) disorders in critically ill patients are common and associated with poor prognosis. The acute gastrointestinal injury (AGI) score was recently designed to assess increasing levels of GI dysfunction. Due to the likely subjectivity in assessing GI symptoms and the lack of uniform definitions/specific biomarkers, the Gastrointestinal Dysfunction Score (GIDS) was developed, aiming to make it more objective and reproducible. However, its validity and reproducibility have not been definitively confirmed. Moreover, higher levels of GI dysfunction also entail greater feeding intolerance (FI), leading to an inability to reach caloric and protein goals.

**Objectives:** To evaluate the progression of gastrointestinal (GI) dysfunction using the AGI and GIDS in relation to hospital mortality in patients on mechanical ventilation (MV). A secondary objective was to evaluate the prognostic variables associated with hospital mortality including both scores and FI.

**Methods:** This is a secondary analysis of a prospective cohort study carried out in 10 ICUs of the public sector in Argentina. Eight hundred patients > 18 years requiring MV and in whom the need for enteral nutrition (EN) for at least 4 days was estimated were included. In each patient enrolled in the study, signs and symptoms of GI, as defined by the ESICM Working Group on Abdominal Problems, were recorded daily. Subsequently, the AGImax and GIDSmax were calculated based on the maximum recorded values.

FI was defined as an average of < 20 kcal/kg received due to GI symptoms, and cumulative caloric debt was calculated within the first week. Both scores were assessed using Kaplan–Meier curves and hospital mortality. Cox regression models were constructed to evaluate independent predictors of mortality. A $p$ value $\leq 0.05$ was considered significant for all comparisons.

**Results:** Characteristics of the 800 patients included: age 45 ± 19; male sex 529 (63); Charlson 0 [0–1]; medical diagnosis 438 (55%); APACHE II 17 ± 6; SOFA 7 [4–9]; shock 426 (52%); ARDS 306 (38%); MV days 11 [7–16]; ICU days 14 [9–40]; hospital mortality 318 (40%). The classification into increasing grades according to AGI/GIDS is shown in Figure 1. In general, increasing grades of AGI/GIDS were associated with greater severity and hospital mortality. In Figure 2, we observe Kaplan–Meier curves for hospital mortality for both scores. Grouping AGI 0–1 vs 2–4

and GIDS 0–1 vs 2–4, we obtained for Hospital mortality OR 11 (CI95% 7.6–11) and 10 (CI95% 7–15), for FI OR 20 (CI95% 13–30) for both scores and for caloric debt mean difference −4405 (CI95% −4026, −4783) and −4293 (CI95% −3912, −4675), respectively. Figure 3 illustrates Cox models considering AGI 2–4 for one model and GIDS 2–4 for the other model as prognostic variables of interest. The two models also incorporated the same variables (age, APACHE II, SOFA, Charlson, medical admission). The AGI model included FI as the nutritional variable, and the GIDS model included caloric debt.

**Conclusions:** Both scores exhibited strong prognostic capability for hospital mortality in severely critically ill mechanically ventilated patients.

There were no major differences when classifying the same cohort with both scores, although the GIDS score placed more patients in grade 2 and differentiated mortality between grades 3 and 4.

With both scores, a substantial difference in mortality, feeding intolerance, and caloric debt was noted when comparing grades 0 and 1 versus 2, 3 and 4.

The adequate prognostic capability, along with other independent mortality factors, highlights the importance of incorporating these scores in selected populations.

**Introduction:** Transesophageal echocardiogram identifies shock and the underlying cause. Provides detailed information and more precise visualization.

**Objectives:** Determine the main indications for TEE in the intensive care unit.

**Methods:** This is a descriptive, prospective study of a sample of 22 patients. The TEE was performed by a critical care resident with prior training of 8.5 h per month.

**Results:** The main indications for TEE were identified: hemodynamic monitoring 52.63%, search for thrombi in the left atrium 26.31%, infective endocarditis 15.78%, VV ECMO cannulation 5.26%; the hemodynamic diagnoses are in Table 1. There were no complications during tube placement. In the field of intensive cardiovascular therapy, the use of TEE generates a modification in treatment and support in decision making, making it an increasingly indispensable instrument. The limitation of the study is due to the sample size.

**Table 1 (abstract 001257)** .

| Characteristics | *n* = 22 |
|---|---|
| Age, median (IQR), years | 53.5 (36–59) |
| TEE indications, *n* (%) | |

### Association of serum creatinine trajectories with one-year mortality after valvular heart surgery: a retrospective cohort study

J. S. Cho[1]
[1]Department of Anesthesiology and Pain Medicine, Yonsei University College of Medicine, Seoul, Republic of Korea
**Correspondence:** J. S. Cho
***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001261

**Introduction:** Acute renal dysfunction is defined by the maximum increase in serum creatinine (sCr) without considering the pattern of change in sCr. We aimed to identify longitudinal patterns (trajectories) of postoperative sCr concentrations and investigate their association with long-term outcomes in patients undergoing valvular heart surgery.
**Methods:** In this retrospective review of 3,436 patients who underwent valvular heart surgery, we applied trajectory projection cluster analysis to identify the trajectories of sCr changes from baseline during the seven postoperative days. Primary and secondary endpoints were to investigate the associations of sCr trajectories with mortality using Kaplan–Meier curves and Cox proportional hazards regression analysis, and a composite of major adverse kidney events (MAKEs) at one year after surgery, respectively.
**Results:** Four clusters were identified: Clusters 1 and 2, a minimal change in sCr (90.1% of patients); Cluster 3, a significant and persistent increase in sCr (4.1% of patients); and Cluster 4, a significant but transient increase in sCr (5.8% of patients). The one-year postoperative mortality rate was higher in Cluster 3 (18.4%) and Cluster 4 (11.6%) than in Cluster 1 + 2 (2.7%). The Kaplan–Meier survival curve demonstrated significant differences in mortality rates among the clusters (log-rank test, $P < 0.001$). In the multivariable Cox analysis, the sCr trajectory cluster was an independent prognostic factor for mortality. Cluster 3 had a higher prevalence of MAKEs (37.6%) compared with Cluster 1 + 2 (6.8%, $P < 0.001$) and Cluster 4 (24.1%, $P = 0.045$). The cluster was an independent prognostic factor for MAKEs.
**Conclusions:** The sCr trajectory clusters exhibited significantly different risks of mortality and MAKEs at one year after surgery. Through these sCr trajectories, we confirmed that both the extent of sCr increase and its sustainability during the first seven postoperative days were closely associated with the long-term prognosis after valvular heart surgery.

### The deletion of Cmtm3 attenuates sepsis-induced ALI through neutrophil modulation

H. Xue[1], Z. Li[2], F. Zhu[1]
[1]Department of Critical Care Medicine, Peking University People's Hospital, Beijing, China; [2]Beijing Key Surgical Basic Research Laboratory of Liver Cirrhosis and Liver Cancer, Peking University People's Hospital, Beijing, China
**Correspondence:** H. Xue
***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001262

**Introduction:** Sepsis is a condition characterized by multi-organ dysfunction caused by the host's dysregulated response to infection (1). Sepsis-induced acute lung injury (ALI) is one of the most common critical illnesses in the intensive care unit, with an extremely high incidence and mortality rate (2). Significant strides have been made in the basic and clinical research of sepsis-induced ALI in recent years. However, clinical management largely remains dependent on supportive care, including anti-infection measures and mechanical ventilation, with a noticeable absence of targeted treatment (3). Thus, exploring the underlying mechanisms of sepsis-induced ALI and identifying potential therapeutic targets is of paramount importance.
Immunological imbalance plays a crucial role in the early stages of sepsis, where neutrophils are implicated in anti-infection activities, inflammatory responses, immune regulation, and tissue damage (4). Their levels and functional states are intimately associated with the progression and prognosis of the disease. In the context of sepsis-induced ALI, neutrophils contribute to defense against infection and microbial clearance but also have the potential to cause or exacerbate inflammation and damage to lung tissue (5). Consequently, research into the regulation of neutrophils and therapeutic strategies is vitally important for improving the outcomes of patients with sepsis-induced ALI.
CKLF-like MARVEL transmembrane domain containing (CMTM)3 belongs to the CMTM superfamily and exhibits widespread expression across the immune system (6). Previous studies have reported that CMTM3 stabilizes the expression of epidermal growth factor receptor (EGFR), VE-Cadherin, and B-cell receptor (BCR) on the cell membrane, thus playing an integral role in the immune response and tumorigenesis (7–9). Our preliminary findings indicate that CMTM3 expression is

upregulated in patients with sepsis-induced ALI. However, the role of CMTM3 in the pathogenesis of sepsis has not yet been reported.

**Objectives:** The objective of this study is to investigate the function and mechanisms of CMTM3 in sepsis-induced ALI and to evaluate the potential role of CMTM3 as a therapeutic target for this condition.

**Methods:** Our study employed bioinformatic analysis and real-time quantitative polymerase chain reaction (RT-QPCR) to determine the expression levels of CMTM3 in cases of sepsis-induced ALI. We generated systemic Cmtm3 gene knockout (KO) mice and established a sepsis model using the cecal ligation and puncture (CLP) method to conduct in vivo experiments. The extent of lung tissue damage was assessed using histological microscopy and RT-QPCR method. Neutrophil infiltration was evaluated through immunohistochemistry (IHC). Lastly, single-cell RNA sequencing (scRNA-seq) of lung tissue from mice was utilized to analyze the specific impact of Cmtm3 deletion on neutrophil populations.

**Results:** We found that CMTM3 is overexpressed in sepsis-induced ALI patients. The knockout of Cmtm3 improved the survival rates and attenuated lung tissue damage in septic mice. Mechanistic analysis indicated that the absence of Cmtm3 reduced neutrophil infiltration in the lung tissue of septic mice. The scRNA-seq analysis revealed significant heterogeneity within the neutrophil populations in lung tissue. They were categorized into three subclusters. Subcluster 1 demonstrated high expression of chemotactic factors. Subcluster 2 was characterized by neutrophil infiltration and activation. Subcluster 3 was distinguished by cell apoptosis and immune regulation. During sepsis, there was a predominant increase in Subcluster 2, whereas Cmtm3 deletion resulted in a reduction of Subcluster 2 and an increase in Subcluster 1 and Subcluster 3.

**Conclusions:** We found that CMTM3 is upregulated in sepsis-induced ALI and may exacerbate lung injury by affecting neutrophil function. The deletion of Cmtm3 shows potential therapeutic value in mitigating ALI in sepsis.

### Evaluation of MACOCHA score for predicting difficult intubation in critically ill cancer patients: a prospective observational study

A. Kulkarni[1], S. Bhosale[2], A. Kothekar[1], A. Shuirvastava[1], M. Gorade[1]
[1]Dept of Anaesthesia, Tata Memorial Centre, Mumbai, India; [2]Department of Anesthesia, Critical Care And Pain, Tata Memorial Centre, Mumbai, India

*Intensive Care Medicine Experimental* 2024, **12(suppl 1):**001264

**Introduction:** Tracheal intubation (TI) is often needed in the ICU but can have disastrous consequences as against when done in OT. The NAP4 audit reported that 25% of complications related to airway management occurred outside the OR, i.e., in the ED and ICUs. MACOCHA, simple 7-item score was described to predict difficult intubation in ICU. We evaluated if MACOCHA score was useful in predicting difficult intubation in critically ill adult cancer patients.
**Methods:** This prospective, observational single-center study was conducted after obtaining IEC approval and waiver for informed consent. We decided to include 500 adults (age > 18 y), whose trachea was intubated in our cancer hospital ICU by trainees with varying backgrounds. Pregnant patients and those patients in whom intubation was required during cardiopulmonary resuscitation were excluded. We collected the demographic data, details of ICU admission, presence of co-morbidities, and intubation related data for calculating MACOCHA score. Details of intubation i.e. indication, preoxygenation, drugs used, attempts at laryngoscopy and intubation, use of Sellick's maneuver were recorded. The complications occurring during and immediately after TI were recorded. We used SPSS software version 21 (SPSS-21; IBM, Chicago, USA) for statistical analysis. The ability and accuracy of the MACOCHA score for predicting difficult intubation was determined by AUC-ROC curve. The Hosmer–Lemeshow goodness-of-fit statistics was used to determine calibration.
**Results:** We analysed data of 449 (of 500 planned) patients due to availability of complete dataset. The mean age of patients was 51 (± 14.31) y, the commonest comorbidities were diabetes, hypertension and cancer therapy, and the commonest reasons for ICU admission were severe sepsis/septic shock and pneumonia. Acute respiratory failure requiring invasive mechanical ventilation, and shock were the most frequent reasons for TI. Most intubation procedures were supervised, and Ketamine was the most commonly used induction agent. Rocuronium was the most commonly used muscle relaxant, while 184 TIs were performed without a muscle relaxant. External laryngeal manipulation was needed in 125 patients, while bougie or stylet was used for TI in 160 patients. One hundred and sixty patients were receiving vasopressor infusion at the time of intubation. Mask ventilation was difficult in six patients, while more than 2 attempts at laryngoscopy and intubation were required in eight and eleven patients, respectively. The incidence of difficult intubation was 13.5% (60/449).

There were 30 patients whose Mallampati score was either III and IV, while 84 and 45 patients had severe hypoxemia and coma before TI, respectively. One hundred and seventy-one (26.5%) complications occurred during TI. Sixty-one patients had severe cardiovascular collapse in the peri-intubation period, while 8 patients died within 24 h of intubation. Nineteen patients had severe hypoxemia during TIThe area under the ROC curve for MACOCHA score was 0.659 (CI: 0.574–0.743) suggesting a moderate discrimination (Figure 1). The MACOCHA score showed sensitivity of 98.5%, specificity 20%, positive predictive value (PPV) 66.7% and the negative predictive value (NPV) was 88.9%. The Hosmer and Lemeshow goodness of fit test showed moderate calibration (X2- 3.142, with $p=0.208$).

**Conclusions:** MACOCHA score in adult critically ill cancer patients showed moderate discriminative ability in predicting difficult intubation in our study. Further studies are warranted to evaluate its utility in predicting difficult intubation so that it can be modified to increase its predictive ability, if required.

***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001267

**Introduction:** Continuous renal replacement therapy (CRRT) is considered to be the main treatment modality of acute kidney injury (AKI) in the Intensive Care Unit (ICU). Various dosages and modes of therapy have been used and lead to unpredicted and frequently suboptimal outcomes.

**Objectives:** The purpose of the present study was to evaluate the effectiveness of CRRT in critically ill patients, in the way it is delivered in the actual conditions of an ICU.

**Methods:** Patients with AKI, who were hospitalized in A' ICU of "G. Papanikolaou" hospital in Thessaloniki between 1/2/2020 and 31/5/2020 and who underwent CRRT, were included in the study. We recorded the demographic data, the severity of illness scores (APACHE II and SOFA), the past medical history, the causes of AKI, as well as data of the session (mode and dose of therapy, blood flow rate, heparin dose, effluent volume, net fluid removal, treatment time, urea and creatinine before and after treatment, and urea reduction ratio—URR).

**Results:** Fifty-seven continuous veno-venous hemodiafiltration (CVVHDF) treatment sessions were performed in 17 critically ill patients. Patients' mean age was $67\pm11$ years and the mean APACHE II and SOFA scores were $24\pm9$ and $10\pm4$, respectively. The cause of AKI was septic shock in the majority of the patients (76.5%). The delivered/prescribed ratio of effluent volume was $0.77\pm0.25$, while the respective ratio of net fluid removal was lower, $0.68\pm0.34$. The mean prescribed therapy dose was $24.2\pm2.9$ ml/kg/h, while the mean delivered dose was $18.6\pm6.8$ ml/kg/h. Overall, the sessions were accomplished in 78%, with the reasons for premature discontinuation of CRRT being mainly the circuit clotting and rarely the hemodynamic instability of the patient. The biochemical markers of kidney function decreased after CRRT (mean difference of urea and creatinine $18.25\pm32.04$ mg/dl and $0.53\pm0.72$ mg/dl, respectively) and the mean value of URR was $13.9\pm22$.

Patients with a history of vascular disease had significantly lower ratios of actual/scheduled operation time, effluent rate and fluid removed per session ($0.67\pm0.23$ vs $0.88\pm0.22$, $p=0.001$, $0.64\pm0.22$ vs $0.88\pm0.23$, $p<0.001$ and $0.52\pm0.26$ vs $0.82\pm0.34$, $p=0.001$, respectively). They also differed significantly, compared to patients without history of vascular disease, in terms of heparin dosage per session ($4.25\pm2.46$ vs $1.61\pm2.28$ IU/kg/h, $p<0.001$) and blood flow per session ($210.74\pm16.39$ vs $225.33\pm23.15$ ml/min, $p=0.008$).

**Conclusions:** Although the application of CRRT in our ICU leads to some degree to the achievement of the therapeutic targets, it should be improved in order to lead to better therapy and patient outcomes. Some issues that deserve special attention are patients with vascular disease, the prescribed therapy dose that could be increased so that the goal be reached in everyday clinical practice and the optimal anticoagulation strategy so that the scheduled treatment time be achieved.

***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001268

**Introduction:** Septic shock is associated with endothelial dysfunction leading to arterial and venous dilation, alterations in regional blood flow distribution, and microcirculatory disturbances. Fluids and vasopressors are the key elements of the hemodynamic support. Vasopressin is recommended by 2021 Surviving Septic Shock guidelines1 as second line vasopressor for patients presenting hypotension refractory to norepinephrine. The proposed cutoff defining refractory hypotension ranges from 0.25 to 0.5 mcg/kg/min but there is no clear indication on the timing of introduction.
**Objectives:** To describe the characteristics of patients admitted to a Critical Care Unit of a tertiary hospital from January 2022 to December 2023 in whom the vasopressin protocol was used in septic shock.
**Methods:** This is a observational, retrospective study in septic patients in the ICU of H.G.U Gregorio Marañón between January 2022 and December 2023. Epidemiological data, comorbidities, clinical characteristics, organ supports used, complications, severity scales, and outcomes were collected.
For descriptive analysis, quantitative variables were expressed as mean with standard deviation if normally distributed, or as median with interquartile range otherwise. Qualitative variables were expressed as percentages.
**Results:** Out of 140 patients, 57% were male. Age: 61 ± 15 years. Medical pathology: 95%, respiratory infection focus 54%, abdominal 22%, urinary 9%, soft tissues 7%, endovascular 6%, and others 2%. Comorbidities: Charlson 2 (1–4). Severity scales: APACHE II at admission 23 ± 7. SOFA at admission 9 ± 3, SOFA at 48 h 9 ± 4. The sepsis bundle was completed within the first hour in 64% of patients. Antibiotic accuracy was achieved in 65%.
Vasopressor use: time to NAD start from sepsis diagnosis 3 h (2–6), NAD dose before starting vasopressin 0.5 ± 0.3, time to Vasopressin start from sepsis diagnosis 8 h (6–11), positive response to vasopressin 73%, total vasopressin use time 28 h (24–48), time to NAD withdrawal after stopping vasopressin 12 h (9–24).
Vital signs: SBP on arrival at the emergency department 92 (81–110), SBP in ICU 110 (90–120). Hemodynamic monitoring: 75% transthoracic echocardiogram, 18% thermodilution, 7% pulse wave. Cardiac dysfunction: normal 70%, mild 10%, moderate 6%, severe 14%.
Volume resuscitation: volume in the initial 24 h 4500 (3500–6000).
Diuresis and balances: first 24 h diuresis 1040 ml (530–1482), positive balance in the first 24 h 94%, negative balance at 48 h only in 41%.
Preload optimization: preload was established to be optimized in 76% of patients before starting VAP. 100% of the series used corticosteroids before starting vasopressin.
Analytical data: pH in ICU 7.31 (7.26–7.41), lactate in ICU 5 ± 4.
Perfusion: lactate clearance in the first 24 h 60%, normalization of capillary refill 61% of the series.
Invasive mechanical ventilation 75%, days of IMV 5 (1–11), only 14% did not have renal failure during their ICU stay. Need for renal replacement therapy 47%.
Complications: 86% had no complications, only 8% had atrial fibrillation, 1.5% had distal ischemia, and 1.5% had mesenteric ischemia.
28-day mortality: 39% of the series. ICU days 9 (5–14), hospitalization days 14 (8–22).
**Conclusions:** Our series presents high severity at admission leading to high mortality, although we observed a favorable response to vasopressin in a large percentage of cases.

***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001269

**Introduction:** The spontaneous breathing trial (SBT) is a cardiovascular (CV) stress test, and failure to wean from mechanical ventilation (MV) often reflects CV insufficiency to cope with the increased oxygen cost of breathing (2). It has recently been shown that non-invasive tissue oxygenation (StO2) parameters were predictive of extubation outcome (1). It has been hypothesized that StO2 changes might reflect the degree of sympathetic response.
**Objectives:** To assess microcirculatory changes and plasma catecholamine levels within a 30-min SBT.
**Methods:** This is a prospective observational single-center study in a 30-bed general ICU. We included patients after at least 48 h of MV, and considered ready to wean by their medical team. Hemodynamic, respiratory, microcirculatory, and plasma catecholamine measurements were taken just before the start of the SBT (pressure support of 8 cmH2O, PEEP 0), and within 30 min of SBT. Microcirculatory evaluation of the brachioradial muscle using the VASCOVID system provided StO2 and microvascular flow (BFi). A vascular occlusion test (VOT) was performed at each time point to obtain StO2 deoxygenation (DeO2), local oxygen consumption (MRO2), StO2 reoxygenation (ReO2) and the StO2 and BFi hyperemic responses. Paired data analysis was performed to evaluate evolutionary changes. Weaning success (successful SBT and extubation) and weaning failure patients (either failed SBT or requiring reintubation within 24 h) were compared.
**Results:** Ten patients were included, 60 ± 17 years, with 6 ± 4 days of MV. Respiratory and hemodynamic stability, FiO2 30 ± 4%, PaO2 77 ± 15 mmHg, HR 92 ± 12 bpm, and MAP 87 ± 18 mmHg, without vasopressor support. Baseline catecholamine levels: NAD 404 ± 310 pg/mL, AD 27 ± 35 pg/mL, and DOP 25 ± 21 pg/mL. Baseline microcirculatory levels: StO2 66 ± 9%, DeO2 -5.6 ± 2.7%/min, ReO2 1.7 ± 1.5%/min, and BFi 8.1 ± 8.4 cm2/sec·10–9.
After the 30-min SBT, no significant changes were detected in catecholamine levels (Figure 1), but microcirculatory changes in local consumption (MRO2) and oxygen extraction (DeO2) were observed (Figure 2). No correlations between changes in plasma catecholamines and microcirculatory changes during the SBT were found.
Two patients failed the SBT, and 8 patients were extubated, one of them requiring reintubation within 12 h. Patients who failed the weaning process had lower baseline levels of NAD and DOP, as well as lower basal StO2 values, with higher oxygen extraction (DeO2). A previously described microcirculatory score (2), combining baseline StO2 and relative changes in DeO2 within the trial, showed significantly different values between patients who succeed and those who failed the weaning process (61 ± 9 vs 43 ± 12%, $p = 0.02$) (Figure 3).
**Conclusions:** Microcirculatory changes occur during the spontaneous breathing trial despite no detectable changes in the plasma catecholamine response. These microcirculatory alterations are non-invasively quantifiable and may have relevant significance in determining the success of the mechanical ventilation withdrawal process.

***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001270

**Introduction:** Although colistin is a widely used antibiotic in the Intensive Care Unit (ICU) for the treatment of multidrug-resistant (MDR) microorganisms, its optimal dosing regimen remains a challenge. This is mainly due to the difficult methodology of its measurement and to its altered pharmacokinetics because of the various pathophysiological changes that seriously ill patients present.
**Objectives:** The purpose of the study was to determine the concentrations of colistin in plasma of ICU patients and to correlate them with the MICs of the bacteria that are most frequently encountered in these patients.
**Methods:** A loading dose of 9 MU of the antibiotic was administered in the first day, followed by 4.5 MU every 12 h, infused in 30 min. Blood samples were drawn just before the start of the infusion, at doses 2 to 6. The method of high-performance liquid chromatography (HPLC) was used to measure colistin concentrations (trough).
**Results:** Six patients were included in this preliminary study with a mean age of 60 ± 14 years. They presented with lower respiratory tract infections and they were treated with colistin either empirically or based on microbiological data. They were all severely ill, with high mean APACHE II (18 ± 7) and SOFA scores (7 ± 1.5) at admission and with no acute kidney injury. Colistin trough concentrations varied widely between patients, with mean values of 0.83 ± 0.45, 0.76 ± 0.44, 0.57 ± 0.35, 0.76 ± 0.41, 0.81 ± 0.54 mg/L, before the administration of the 2nd, 3rd, 4th, 5th and 6th dose, respectively. By administering the loading dose, the steady state of the antibiotic was achieved quickly. In half of the patients, colistin levels were maintained > 0.5 mg/L at all timepoints, which is the usual MIC of the MDR bacteria in our ICU.

**Conclusions:** Colistin, administered at the recommended dose, presents broad and frequently inadequate variations of its levels in ICU patients. Notably, it reaches quickly the steady state.

**Correspondence:** J. Boelens
***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001271

**Introduction:** Early reporting of antimicrobial susceptibility testing (AST) results for patients with bacteremia remains an important challenge for microbiology labs. Available solutions are incomplete, not always adapted to local antimicrobial resistance epidemiology, labor-intensive or expensive.
Recently, growth-based AST systems for Gram-negatives from positive blood cultures have become commercially available. We studied the clinical impact in antimicrobial decisions following acquisition of rapid AST results obtained with the ASTar-system (Q-Linea, Uppsala, Sweden).
**Methods:** We performed a prospective real-life clinical study in a + 800 beds tertiary care teaching hospital; we studied consecutive patients with Gram-negative bacteremia. AST was performed using the ASTAR system which provides MIC-values and EUCAST categorical interpretation for monomicrobial Gram negative blood cultures after 6 h (versus at least 24 h for regular AST). Results were reported in real time in the electronic medical record of the patient in combination with active antimicrobial stewardship interventions (including a telephone call and discussion at the daily multidisciplinary infection meeting). We studied the interval to effective and optimal antimicrobial therapy. Effective therapy was defined as an antimicrobial with confirmed susceptibility against the isolated Gram-negative rod. The antimicrobial therapy was considered optimal when it was the least broad antimicrobial, without unnecessary anaerobic or Pseudomonas coverage, or when a suitable oral option was administered. The study was approved by the ethics committee and informed consent was obtained.
**Results:** Over an 8-week period, we included 40 patients (22 males) with 1 or 2 episodes of Gram-negative bacteremia. Age of the patients varied between 0 and 91 years. Out of these 43 episodes of bacteremia, ASTar could determine susceptibility in 40 episodes; no MIC interpretation was available in 2 episodes because of insufficient growth, and in 1 episode (*Acinetobacter junii)* interpretation of the MIC-results was not possible.
In the 40 episodes in which AST was reported, antimicrobial resistance for the empirical antimicrobial therapy was detected in 6 patients (15%). In these patients, effective antimicrobial therapy was started within a median time of one hour and 13 min after releasing the result (12 min–6 h 22 min). In 31 episodes, the ASTar susceptibility results allowed for downgrading the empirical antimicrobial therapy. The advice for downgrading was followed in 16 cases (40%) after a median time of 3 h and 40 min. Reasons for not downgrading therapy included the lack of source control, unknown focus of infection or neutropenia. In 3 episodes, no adaptations were made as the empirical therapy was considered optimal, following the definition in the methods section (8%).
**Conclusions:** The implementation of more fast AST reporting for Gram-negative bacteremias in combination with the multidisciplinary approach and multi-modal communication resulted in the initiation of effective antimicrobial therapy within a median time of one hour and 13 min after communication of the ASTar-results and the adaptation to optimal therapy after a median time of 3 h and 40 min.

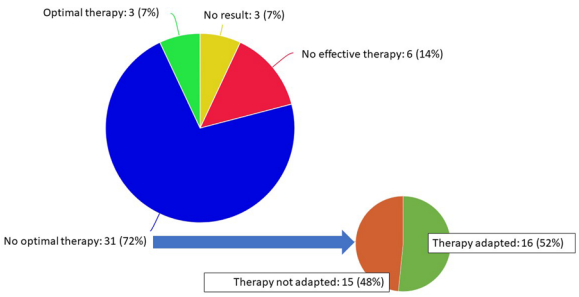

**Fig. 1 (abstract 001271)** Overview of ranges of optimal and effective therapies and the rapid adaptation of therapy

### Sarcopenia index to evaluate muscle mass and function in critically ill older adult trauma patients

K. Haines[1], J. Molinger[2], K. Schmader[3], C. E. Cox[3], N. E. Deutz[4], M. Engelen[5], F. M. Fernandez[1], S. Agarwal[1], W. Paul[1]
[1]Department of Surgery, Duke University, Durham, NC, USA, Durham, United States of America; [2]Department of Anesthesia, Duke University, Durham, NC, USA, Durham, United States of America; [3]Department of Medicine, Duke University, Durham, NC, USA, Durham, United States of America; [4]Department of Health and Kinesiology, Texas A&M University, College Station, United States of America; [5]Kinesiology and Sport Management, Texas A&M University, College Station, United States of America
**Correspondence:** K. Haines
***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001272

**Introduction:** Sarcopenia, characterized by the loss of skeletal muscle mass and strength, is prevalent among aging individuals, defined here as adults ages 60 and older. While traditional assessments for sarcopenia rely on various measurements such as muscle mass, strength, and physical performance, the Sarcopenia Index (SI) offers an alternative yet underutilized approach. The SI, which compares serum creatinine to cystatin C levels, provides an indirect assessment of muscle mass, particularly valuable in situations where direct measurement is challenging.
**Objectives:** This study aimed to explore the potential of the SI as a surrogate marker for traditional measures of malnutrition, sarcopenia, and functional status in older adult trauma patients.
**Methods:** A prospective observational study enrolled 40 older adult trauma patients upon admission. Functional measures, self-reported health, creatinine, cystatin C for SI, and MuscleSound data were collected. A multivariable regression model assessed the relationship between the SI and functional measures, including the 6-min walk distance (6MWD), 4-m walk (4 MW), 30-s sit-to-stand test, and grip strength, controlling for age and BMI.
**Results:** Of the 40 enrolled patients, 38 had baseline SI and functional measures. The mean age was 73 (SD 9.1) yr, with 62.5% females and 37.5% males. The majority had a BMI of 29 (SD 6.7) kg/m2, and the mean SI was 88 (SD 19). MNBA classified 20 participants as nourished and 16 as at risk of malnutrition or malnourished. Self-reported health was reported as good (28%), fair (61%), and poor (4%) on admission. In a multivariate regression analysis controlling for age and BMI, the SI was predictive of the MNA, SARC-F, 30-s sit-to-stand, 4-m walk, 6-min walk distance, and grip strength outcomes.

**Conclusions:** The study underscores the potential of the serum SI as a surrogate marker for malnutrition, sarcopenia, and functional status in older adult trauma patients. By providing an indirect assessment of muscle mass, the SI offers valuable insights into patient outcomes and may enhance clinical management strategies for this population. Further research is warranted to validate these findings and explore the utility of SI in clinical practice.

### Impaired muscle function years after critical illness: a transcriptomics quest for underlying mechanisms

C. Uzun[1], F. Güiza[1], I. Derese[2], M. Casaer[3], G. Hermans[4], P. Wouters[1], G. Van den Berghe[3], I. Vanhorebeek[1]
[1]Laboratory of Intensive Care Medicine, Department of Cellular and Molecular Medicine, KU Leuven, Leuven, Belgium; [2]Laboratory of Intensive Care Medicine, KU Leuven, Leuven, Belgium; [3]Laboratory of Intensive Care Medicine, Clinical Division of Intensive Care Medicine, KU Leuven, Leuven, Belgium; [4]Laboratory of Intensive Care Medicine, Medical Intensive Care Unit, Katholieke Universiteit Leuven, Leuven, Belgium
**Correspondence:** C. Uzun
***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001273

**Introduction:** Critically ill patients are at high risk of developing muscle weakness during their stay in the intensive care unit (ICU), which is associated with adverse short-term outcomes. Improved survival of critical illness with advances in intensive care revealed that a substantial proportion of the patients show persistent physical impairments up to years after hospital discharge, compromising quality of life [1–3]. Whereas major insight has been gained in the pathophysiology of ICU-acquired weakness, the pathophysiology of long-term weakness years after critical illness remains unclear. We previously performed a long-term follow-up of former critically ill patients in the context of the EPaNIC study, showing lower strength, worse functional capacity and worse self-reported physical function in former patients 5 years after ICU admission as compared with matched control subjects [4,5]. Availability of muscle biopsies of a subgroup of these participants provides a unique opportunity to study potential underlying mechanisms of the long-term physical impairments.
**Methods:** We analyzed the muscle transcriptome of 120 former ICU patients 5 years after critical illness and 30 matched controls via RNA sequencing. We identified differentially expressed RNAs with the R package DESeq2 [6], adjusting for age, sex and BMI and applying a false discovery rate (FDR) < 0.05. We further conducted pathway and gene set enrichment analyses to study the functions of the identified differentially expressed genes (DEGs) applying an FDR < 0.05 and performed a differential co-expression analysis of the DEGs.
**Results:** Good quality data were obtained for 115 former ICU patients and 30 matched controls. After excluding transcripts with too low read count, 16,685 transcripts remained for analysis. We identified 109 upregulated and 233 downregulated RNAs (-4.5 to 2.6 log2-fold changes) in former ICU patients, including 33 non-coding RNAs. Pathway analysis revealed that the upregulated DEGs were enriched in AMPK and PPAR signaling as well as collagen formation pathways, while downregulated DEGs showed enrichment in mitochondrial ATP synthesis/cellular respiration pathways. Gene set enrichment analysis indicated a downregulation of oxidative phosphorylation.
**Conclusions:** The observed distinct gene expression profile 5 years after critical illness as compared with controls may suggest effects on adiposity and fibrosis within muscle as well as impaired muscle metabolism due to disrupted mitochondrial function, to be investigated in further histological and molecular studies. Whether the abnormal transcriptomic profile correlates with adverse physical outcomes of the former ICU patients also remains to be investigated.

***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001275

**Introduction:** Patients with severe ARDS need to be transferred in a center with an ECMO-based management protocol to significantly improve survival. Moreover, ECMO patients, are at high risk of hospital-acquired infections (HAIs) caused by multi-drug resistant bacteria (MDRb) (32–50%). No data are available on MDRb incidence and outcomes in patients supported with ECMO started on-site and then referred to regional center.
**Objectives:** Primary endpoint: incidence of MDRb in ECMO referral group. Secondary endpoints: role of MDR infections on multiorgan failure (MOF) and mortality in overall ECMO population.
**Methods:** This is a retrospective observational monocentric study conducted in the ICU of the University Hospital of Sassari. Inclusion criteria: patients with severe ARDS and refractory hypoxemia treated with V-V ECMO.
**Results:** From January 2017 to March 2024, 24 consecutive patients were recruited. 83.3% were male with mean age $51 \pm 10.7$ and BMI

31.9 ± 8.6. 50% of patients underwent to 3.4 ± 4 days of NIV Pre-MV and the mean VM was 42.7 ± 23.9 days. 25% of patients presented severe ARDS COVID-19 related and 37.5% received ECMO onsite by our team and then referred to our Regional Center. MDRb were isolated in 75% of ARDS patients enrolled (86% in COVID -19 population); in the referred group, incidence was 66.6%. Klebsiella pneumoniae was the most representative MDRb. Respiratory parameters, isolation sites and organ support therapies are summarized in Table 1. Overall, ICU mortality at 60 days was 45.8% with MDRb incidence of 63.6%, while in the referral group, 33.3% died all presenting MDRb infection.

| **ECMO V-V** | ***(n = 24)*** | | |
|---|---|---|---|
| Respiratory monitoring | *Mean (SD)* | | |
| | P/F | Pplat | CStat |
| Before-ECMO | 69,8 (12.3) | 28 (3.3) | 34 (14.1) |
| During ECMO | 193 (84) | 26 (2.5) | – |
| Infections | Overall n. 24 | | Referral during ECMO n. 9 |
| SOFA score at ICU Admission | 9.5 (4) | | 9 (3) |
| ECMO days | 19.4 (15.2) | | 14.8 (8.3) |
| PCT | 8 (10.4) | | 8 (12) |
| SOFA score | 10 (3.1) | | 10 (3) |
| mdr *n (%)* | 18 (75) | | 6 (66.6) |
| Klebsiella pneumoniae | 11 (45.8) | | 3 (33.3) |
| Pseudomonas aeruginosa | 3 (12.5) | | 0 |
| Acinetobacter | 4 (16.7) | | 2 (22.2) |
| E. coli | 1 (4.2) | | 1 (11.1) |
| MRSE | 5 (20.8) | | 0 |
| Candida species | 5 (71) | | 2 (22.2) |
| Microbial Cultures | | | |
| BAL | 17 (70.8) | | 6 (66.7) |
| Bloodstream | 10 (41.7) | | 1 (4.2) |
| Screening SCPE | 9 (37.5) | | 4 (44.4) |
| CVC | 6 (25) | | 1 (11.1) |
| Urine | 7 (29.2) | | 4 (44.4) |
| Organ support therapy | | | |
| Norepinephrine | 22 (91.7) | | 7 (77.8) |
| RRT | 14 (58.3) | | 5 (55.6) |

**Conclusions:** Our study confirms that V-V ECMO ARDS patients are at increased risk of MDRb infection with potential correlation to worst outcomes. However, starting ECMO support on site and then transferring to a referral center does not seem to affect outcome, although the sample size was small. Further evidence from high-quality prospective studies are warranted to better guide clinicians during the decision-making process.

### Vasopressor dependency as a predictor of mortality in septic shock patients in intensive care unit: a prospective observational study in a tertiary care hospital

P. Sagarika[1], S. B. Mishra[2], M. K. Ali[2], S. Samal[2]
[1]Critical Care Medicine, Institute of Medical Sciences and Sum Hospital, Bhubaneswar, India; [2]Department of Critical Care Medicine, IMS and SUM Hospital, Bhubaneswar, India
**Correspondence:** P. Sagarika

***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001276

**Introduction:** Septic shock ensues when sepsis-induced hypotension remains refractory to fluid resuscitation. Mean arterial pressure is the key determinant of increased tissue blood flow and perfusion. The guideline recommends an initial target mean arterial pressure (MAP) of 65 mm Hg over higher MAP targets. (3) Effective fluid resuscitation and vasopressor are mainstay for maintaining the target MAP. The hemodynamic response of vasopressors to achieve a target MAP can be measured by vasopressor dependency (VD).
**Objectives:** To estimate the correlation between:
1. Vasopressor dependency with 28-day mortality.
2. Vasopressor dependency with organ failure (delta SOFA score).

**Methods:** This is a prospective observational study conducted over a period of 6 months, i.e. September 2023 to February 2024. All consecutive adult patients (> 18 years) with a diagnosis of septic shock were included in the study. Septic shock was diagnosed as per the sepsis-3 criteria by the treating physician. Lowest MAP during the first 24 h after inclusion to the study was recorded.
Vasopressor inotrope score (VI) was calculated using the following formula:
(Dose of dopamine1) + (Dose of dobutamine1) + (Dose of epinephrine100) + (Dose of norepinephrine100) + (Dose of phenylephrine100) + (Dose of vasopressin10).
All doses are in mcg/Kg/min except vasopressin, which is unit/hour.
Maximum value of vasopressor in the first 24 h was taken for calculation of VI.
Vasopressor dependency (VD) was calculated as VD = (VI/MAP) 100.
Patients were categorized into three groups according to the VD score, such as VD of < 0.5/mmHg as mild (VD1), 0.5 to 1/mmHg as moderate (VD2) and > 1/mm Hg as severe (VD3).
**Results:** Thirty-four patients (34) of median age (55 with IQR 33–66) were included in this study during this period. Demographic parameters and length of ICU stay are summarised in Table 1. 28-day mortality rate in VD1, VD2 and VD3 was 50%, 50% and 72%, respectively.
**Conclusions:** In this prospective observational study, we found that in adult septic shock patients, the 28-day mortality is higher in severe vasopressor-dependent group.

***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001277

**Introduction:** Invasive infections by *Streptococcus pyogenes* have become increasingly common in recent years. These infections can range in severity and are more resistant to macrolides and quinolones due to their overuse. As a result, there are fewer treatment options available, which can lead to a poor prognosis.

**Objectives:** Evaluate the demographic, clinical, and microbiological characteristics of *Streptococcus pyogenes* infections in the province of Guadalajara, Spain.

**Methods:** The study was conducted as a retrospective descriptive study of individuals over 16 years old with documented *Streptococcus pyogenes* infection by cultures from January to December 2023.

**Results:** We included 95 patients with a microbiological diagnosis of *Streptococcus pyogenes* cultures. 57.89% of those were women, with a median age of 49.91 years (±18.51). The most frequent clinical syndromes were otorhinolaryngological infections (38.95%), skin and soft tissue infections (32.63%), necrotizing fasciitis (8.42%), pneumonia (8.42%), and gynecological infections (7.37%). Of all infections, 35.79% required hospitalization, with an average length of stay of 17 days (±22.9) and an APACHE II score of 8.6. 12.63% of the patients were admitted to the ICU, with an average length of stay of 17.6 days (±32.03) and an APACHE II score of 15.83. The overall mortality rate was 6.31%. The most commonly altered analytical parameters were leukocytes 13,777/uL (±7,784), C-reactive protein 218.36 mg/L (±156.43), and procalcitonin 34.98 ng/mL (±12.5). The time of administration of antibiotics was 12.31 days (±8.66), intravenously 11.57 days (±12.11), and orally for 9.22 days (±4.49). Focus control was performed in 38.95% of patients, of which 37.84% required surgical intervention. Organic failure occurred in 18.94% patients and immunoglobulins were administered in 4.21% patients (meeting criteria for toxic shock syndrome).The antibiotic susceptibility profile of the isolates was: universally sensitive to penicillins and aminopenicillins with or without beta-lactamase inhibitors. The bacteria was 89.41% sensitive to clindamycin, 91.8% sensitive to quinolones, 65.52% sensitive to macrolides, and 97.22% sensitive to trimethoprim/sulfamethoxazole.

**Conclusions:** Infections caused by *Streptococcus pyogenes* in the province of Guadalajara present a variety of clinical manifestations, with otorhinolaryngological and soft tissue infections being the most common. Despite high susceptibility to certain antibiotics such as penicillins and cephalosporins, increasing resistance to macrolides and quinolones underscores the need for judicious use of antibiotics to preserve treatment efficacy. Mortality rates associated with *Streptococcuspyogenes* infections remain significant, especially among patients admitted to the intensive care unit. Therefore, it is essential to provide appropriate clinical and therapeutic management to improve patient outcomes.

### Influence of fluid balance on the success of support pressure ventilation in mechanically ventilated critical patients without ARDS

A. Sellas[1], F. Oller[1], A. Fernández-Olivares[2], O. Peñuelas[3], A. Muriel[4], A. Esteban[3], F. Frutos-Vivar[3], O. Roca[1]

***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001278

**Introduction:** Early transition from controlled to pressure support ventilation (PSV) may decrease the duration of mechanical ventilation (MV) and the risk of associated complications, potentially improving clinical outcomes in critically ill patients. Conversely, initiating spontaneous breathing prematurely may have adverse consequences. Several risk factors have been shown to predict PSV failure. However, the impact of fluid balance (FB) on PSV outcomes in non-ARDS patients remains unclear.
**Objectives:** To evaluate the influence of fluid balance (FB) on the failure of PSV in critically ill intubated non-ARDS patients.
**Methods:** This is a secondary analysis of a multicentric prospective observational study that included adult patients admitted to 534 ICUs across 32 countries requiring invasive mechanical ventilation (MV). We included patients who did not meet ARDS criteria at the time of intubation and in whom PSV was initiated between the 3rd and 7th day of ICU admission. Patients were excluded if fluid balance 48 h prior to the transition to PSV was unknown. PSV failure was defined as the need to relapse to a controlled mode of MV within 48 h after PSV onset. A multivariate analysis with binary logistic regression was performed to analyze the influence of FB on PSV failure, including as covariates all those variables that had a $p$-value < 0.1 in the univariate analysis. FB was categorized into tertiles.
**Results:** A total of 1020 patients were included. PSV failed in 435 (42.6%) patients. The median duration of MV prior to the transition to PSV was 4 (IQR 3–5) days. PSV failure was associated with higher 28-day mortality, longer duration of MV, and ICU stay (Table 1). After adjusting for possible covariables (age, SAPS II, reason for MV, leukocyte count, level of PEEP, and respiratory rate at PSV onset), a FB > 2112 ml in the 48 h prior to PSV onset was associated with a higher risk of PSV failure (OR 1.44 [95%CI 1.04–2.00]).
**Conclusions:** PSV failure was frequent among non-ARDS patients, and it was associated with positive fluid balance in the 48 h prior to PSV initiation. These findings highlight the importance of fluid management in critically ill patients, suggesting that limiting positive fluid balance could potentially improve PSV success rates and patient outcomes.

**Table 1 (abstract 001278)** Outcomes. LOS: length of stay; PS: pressure support; MV: mechanical ventilation. Data are expressed as median (IQR) or frequency (percentage)

| Variable | All | PS success | PS failure | p-value |
|---|---|---|---|---|
| | = 1020 | n = 585 | n = 435 | |
| ICU LOS | 11 (8-19) | 9 (7-14) | 16 (10-25) | <0.001 |
| Hospital LOS | 23 (14-39) | 23 (14-38) | 25 (14-40) | 0.8 |
| Days of MV | 7 (5-11) | 6 (4-8) | 9 (6-15) | <0.001 |
| Mortality at day 28 | 235 (23%) | 27 (5%) | 208 (48%) | <0.001 |

***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001280

**Introduction:** Bronchoscopy is a medical procedure frequently performed in intubated, critically ill patients. It carries inherent risks, such as worsening hypoxemia and CO2 accumulation, which depend upon the operator's expertise. Prioritizing patient safety necessitates comprehensive training of clinical staff in this area. Simulation-based training emerges as an effective, risk-free modality for procedural education.
**Objectives:** This study aims to develop a real-time image recognition software tailored to identify the major tracheobronchial structures and to demonstrate the non-inferiority of this artificial intelligence-based (AI) compared to traditional training.
**Methods:** Bronchoscopy procedures were performed using a video flexible bronchoscope "Insighters iS3-C5" (SEDA S.p.A., Italy), on TruCorp AirSim Advance X model (Lurgan, Co., North Ireland), an orally intubated manikin with high fidelity bronchial branches. An image recognition software was developed, using YOLOv8 neuronal network, for the recognition of the tracheobronchial structures. Model performance was evaluated using a Confusion Matrix.
A cohort of 22 second-year residents naïve in bronchoscopy procedures underwent theoretical training. Residents were divided into two groups to participate in 20 min of individual practical training. The first group was supervised by an expert, while the other was guided by the AI-based software. Before and after the practical training, residents were evaluated using a modified-BSTAT test, a tool designed to assess their performance during bronchoscopy. Test results were analyzed via Student's t-test. Data are reported as mean ± standard deviation.
**Results:** The ability of the AI-based software to predict the correct tracheobronchial structures is described in Figure 1. Notably, the sensitivity was high, ranging between 0.89 and 1.0. Results of the Pre and Post-training modified-BSTAT are reported in Table 1. No differences between the two groups were observed in terms of pre- and post-training scores.
**Conclusions:** Our AI-based image-recognition software is able to correctly identify the tracheobronchial structures and could be a valuable educational tool for bronchoscopy training.

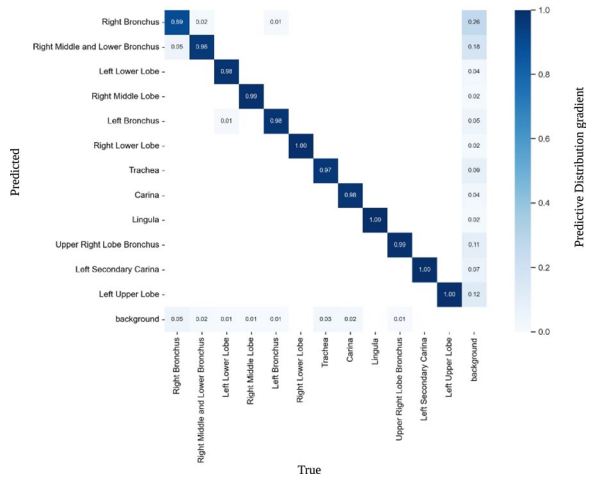

**Fig. 1 (abstract 001280)** Normalized confusion matrix for image recognition of main tracheobronchial structures

**Table 1 (abstract 001280)** Results of the modified-BSTAT examination, divided into pre (before the training) and post (after the training). Data are presented as mean ± standard deviation

| | | Traditional training | AI-based training | P-value |
|---|---|---|---|---|
| Pre-training | Score (points) | 29 ± 4 | 31 ± 5 | 0.49 |
| | Knowledge (points) | 18 ± 3 | 18 ± 2 | 0.87 |
| | Practical skills (points) | 13 ± 3 | 12 ± 2 | 0.44 |

*Intensive Care Medicine Experimental* 2024, **12(suppl 1):**001281

**Introduction:** Whole-body amino acid plasma rate of appearance (WbRa) in health and disease has predominantly been calculated using primed-constant and continuous stable isotope infusion of phenylalanine (PHE) and tyrosine (TYR). We used a new pulse tracer approach to compare the Ra and intracellular production of PHE and TYR to investigate the balance between protein breakdown rate and dietary protein intake in critically ill patients.
**Methods:** (Net) protein breakdown in the postabsorptive condition was measured in 51 ICU (~60 y, 15f, SOFA: 6.6) patients and 49 matched healthy individuals (~50 y, 22 f) using the pulse stable tracer approach with L-[ring-13C6]PHE and L-[ring-2H4]TYR stable isotopes (Posthoc Analysis ref1-3). We calculated both the intracellular production (compartmental analysis) of PHE and the WbRa. PHE to TYR conversion was used to calculate net protein loss. Data are mean [95% CI], stats: t-test (Prism).
**Results:** Daily protein breakdown, using WbRa data, was lower in the healthy than in the ICU group (292 [286, 305] vs ICU: 411 [398, 424] gram protein/individual ($P < 0.0001$), respectively). However, when calculating intracellular production, the absolute daily protein breakdown was much higher in both groups (healthy: 642 [592, 691] versus ICU: 892 [825, 960] gram protein/individual ($p < 0.0001$)). Consequently, lower values were found for net protein loss using both WbRa (Healthy: 44 [42, 47], ICU: 31 [29, 33], $p < 0.0001$) and intracellular production (Healthy: 87 [82, 92], ICU: 60 [56, 65] gram protein/day/individual, $p < 0.0001$). Using net intracellular protein loss when no food is provided, daily lean body mass loss was calculated to be in healthy versus critically ill (577 [544, 611] vs ICU: 402 [373, 431] gram/individual, respectively ($p < 0.0001$).
**Conclusions:** We conclude that using the estimation of daily human (net) protein breakdown from the plasma rate of appearance (WbRa) as was done in the past is too low both in healthy and ICU patients. We suggest using compartmental analysis after pulse tracer to better estimate protein breakdown rates.

***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001282

**Introduction:** Catheter-associated urinary tract infection (CAUTI) remains a significant concern, particularly among kidney transplant patients (KT), as it contributes to prolonged hospital stays, increased costs, and elevated morbidity and mortality rates (1).CAUTIs represent approximately 9% of all hospital-acquired infections, with an estimated 65%–70% deemed preventable (2). However, consensus regarding the optimal timing for catheter removal in KT patients is lacking (3). Since 2021, our center implemented a CAUTI prevention bundle, followed by a nursing-led initiative in early 2024 to address rates and empower staff.
**Objectives:** The objective of this study is to assess the appropriateness of indwelling urinary catheter (IUC) use and to evaluate the timely removal of catheters in KT.
**Methods:** A group of nurses conducted a retrospective review of CAUTI cases from 2021 to 2023, focusing on KT patients. The review aimed to assess catheter promptness removal according to internal policies based on HICPAC 2009 guidelines. Infection rate was calculated per 1,000 catheter days. Adherence to early device removal within 5 days post-transplant was evaluated. Descriptive statistics and a quality improvement plan were provided.
**Results:** A total of 203 kidney transplant (KT) patients were evaluated, with 16 (7.8%) diagnosed with catheter-associated urinary tract infection (CAUTI): 5 cases in 2021 (1.8%), 4 in 2022 (1.86%), and 7 in 2023 (2.83%). The average timeframe between Foley catheter insertion and infection onset was 9.19 days (standard deviation ± 3.69; 95% CI 7.38–10.99). All identified pathogens were classified as Gram-negative (refer to Table 1–2), with 8 being multidrug-resistant organisms. Among the 16 CAUTI cases, 2 were in the ICU and 14 in a step-down unit. None of these patients had their indwelling urinary catheter (IUC) removed within 5 days post-transplant, and 7 subsequently developed sepsis. Of the 16 patients, 9 (56.2%) met the criteria for retaining their IUC: 4 met the 5th criterion, 3 the 7th, 1 the 1st, and 1 case did not have the IUC removed due to critical clinical condition. Conversely, 7 cases (43.7%) did not meet the criteria for retaining the IUC. Criteria for catheter removal (refer to Table 3) show 56.2% of patients meeting them, while 43.7% do not. Monthly educational sessions were organized to provide additional training for nurses on evidence-based practices (EBP) and to underscore the importance of adhering to bundles and nurse-driven protocols. In addition, posters outlining the bundles were created to promote adherence to CAUTI prevention among bedside staff.
**Conclusions:** Empowering nurses to make decisions on early catheter removal enhances patient care and nurse engagement in CAUTI prevention efforts (4,5). Implementing a nurse-driven protocol as part of a comprehensive intervention strategy fosters evidence-based decision-making, ensuring timely removal and empowering nursing staff.

**Introduction:** Obesity is a chronic disease and a significant health problem that is associated with serious medical conditions, increased morbidity and mortality. The influence of obesity on outcomes in critically ill patients is being debated, as some studies have shown increased mortality and morbidity, while others have suggested a decrease in these rates or no association.
**Objectives:** This study aimed to evaluate the impact of Body Mass Index on the outcome of critically ill patients.
**Methods:** This retrospective single-center study included patients admitted to the Intensive Care Unit (ICU) between 2019 and 2023. The patients were categorized into four groups based on their Body Mass Index (BMI) (underweight: < 18.5; normal weight: 18.6–24.9; overweight: 25.0–29.9; obese: > 30 kg/m$^2$). Clinical and demographic data were collected, and the primary endpoint was to evaluate whether a higher BMI is associated with increased hospital mortality. The secondary endpoints were to assess whether a higher BMI is linked to increased ICU mortality, a longer duration of mechanical ventilation and an extended hospital stay in the ICU.
**Results:** A total of 3,042 patients were included in the study. The patients had a median age of 66.0 (55.0–75.0) years, with 62.0% being male and a mean BMI of 26.0 (23.0–31.0). The mean APACHE II score was 20.0 (15.0–26.0) and SAPS II was 49.0 (38.0–62.0). Of the admitted patients, 2.7% were underweight, 30.2% had a normal weight, 38.6% were overweight, and 28.4% were obese, with corresponding mortality rates of 42.8%, 40.0%, 41.6%, and 41.6%, resulting in an overall hospital mortality rate of 41.2%.
There was no significant difference in hospital mortality among the four BMI groups ($p = 0.606$) (Graph 1). BMI was also not associated with increased ICU mortality ($p = 0.091$), length of hospital stay ($p = 0.474$) or duration of mechanical ventilation ($p = 0.805$). However, we did find that higher BMI was associated with a longer duration of ICU stay ($p = 0.023$).
**Conclusions:** In this population, BMI did not influence hospital mortality. Although obesity has been considered a risk factor for mortality in critically ill patients, this increased risk was not evident in our study population. Nevertheless, higher BMI appears to be associated with an extended duration of ICU hospitalization.

**Introduction:** Resuscitation protocols in critically ill patients are based on the administration of fluids and vasopressor drugs. According to the guidelines, the vasopressor drug that is primarily used in all patients with hemodynamic instability is noradrenaline. In recent years, a new vasopressor drug, vasopressin, has been recommended to be added to septic patients who need a small to moderate dose of noradrenaline to reduce the negative effects of circulating catecholamines at increased concentration.
**Objectives:** The purpose of the present study is to investigate the effect of early administration of vasopressin (as a first vasoconstrictor drug) over noradrenaline on the degree of multi-organ failure, in critically ill patients with a need for circulatory support with vasoactive drugs.

**Methods:** A randomized-controlled study was conducted. In group 1, vasopressin (VASg) was administered up 0.03 IU/min (2.3 ml/h), aiming a mean arterial pressure of 65 mmHg. If not reached, noradrenaline was started. In group 2, noradrenaline (NAg) was started first, up to 0.5 mcg/kg/min and if needed, vasopressin was initiated, up to 0.03 IU/min (2.3 ml/h). The primary endpoint of the study was the effect of the early administration of vasopressin, in multiorgan function assessed with SOFA score.
**Results:** Twenty-eight patients were included, of which 17 (60%) were allocated to the Vasopressin group and 12 (40%) to the Noradrenaline group. The median age was 60 (52.5, 67) vs 68.5 (53.25, 77.25, $p=0.303$, APACHE II 22.5 (15.75, 22.5) vs 29 (25, 33), $p=0.020$, SOFA 11 (9.5, 12.5) vs 11.5 (10.25, 13), $p=0.283$ in VASg and Nag, respectively. Septic, hemorrhagic and vasodilatory (apart from septic) types of shock were equally distributed in both groups (16.7% vs 12.5%, 8.3% vs 6.3%, $p=0.879$, 6.3% vs 33.3%, $p=0.133$, respectively). All patients in VASg received vasopressin at the highest dose vs 10 patients in the NAg, and the median noradrenaline dose (needed in 16/17 patients) was 1.79 (0.93, 4.2) vs 0.65 (0.37, 4.55), µg/kg/min, $p=0.294$. In VASg, SOFA score was significantly lower in Day 5 [4 (2, 8.75) vs 11 (9.5, 12.5)], $p=0.007$] and Day 7 [2.5 (2, 7) vs 11 (9.5, 12.5), $p=0.001$] compared to Day 0, while the SOFA score did not present significant differences during the subsequent days in the NAg [Day 3, 10 (4.75, 14.5) vs 11.5 (10.25, 13), $p=1.000$; Day 5, 6 (3.5, 13.25) vs 11.5 (10.25, 13), $p=0.483$; Day 7, 6 (3.5, 13.25), $p=0.853$].
The median duration of vasopressin administration was 2 (2, 4) vs 2.5 (0, 7.5) days, $p=0.777$ and of Noradrenaline administration was 2 (0.5, 4) vs 4.5 (2, 10.5) days, $p=0.107$, respectively. 28-day survival was 88.2 vs 58.3%, in the VASg and Nag, respectively, (Log Rank $p=0.056$).
**Conclusions:** Vasopressin seems an attractive first option in the management of circulatory failure, in terms of multiorgan function improvement. Further research is needed.

***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001289

**Introduction:** Nosocomial infections are a serious concern for critically injured patients who are hospitalized in the intensive care unit (ICU). Unfortunately, the risk factors that contribute to these infections are not well understood.
**Objectives:** To identify the primary risk factors of nosocomial infection after severe traumatic injury.
**Methods:** It was a descriptive, observational study of all patients aged over 18 years admitted for severe traumatic injuries in the medical ICU of Zaghouan's regional hospital between January 2019 and June 2023. Demographic, clinical, therapeutic and evolutionary data were collected. Risk factors of nosocomial infections were later determined.
**Results:** We included 117 patients. Mean age was $40\pm17$ years with a gender ratio of 8. Median IGSII and APACHEII scores were, respectively, 20 [12–56] and 9 [12–41]. Ninety-seven patients suffered from head trauma (83%), 83 from chest trauma (71%) and 49 from abdominal trauma (42%). Nosocomial infections were diagnosed in 32% of patients during their ICU stay on day $5\pm3$ of care. These were mainly ventilator-associated pneumonia (81%), followed by bacteremia (32.4%), urinary tract infections, catheter-related infections (13.5%) and neuro-meningeal infections (10.8%). These nosocomial infections were complicated by septic shock in 12% of cases. The univariate analysis identified the presence of comorbidities, lesion status, and hospitalization-related complications as the primary contributors. The observed risk factors included high blood pressure ($p=0.003$), cerebral contusion ($p=0.026$), haemothorax ($p<103$), status epilepticus ($p<103$), use of vasopressors at admission ($p=0.006$), invasive mechanical ventilation ($p=0.006$) or need to tracheostomy ($p=0.005$), acute respiratory distress syndrome ($p=0.020$), bedsores ($p<103$), and intensive care related neuromyopathy ($p=0.003$). Using receiver operating characteristic (ROC) curves and cutoffs, we found that performing a body scan after 1 h and 30 min of management (AUC = 0.70, 95% CI [0.52–0.88], $p=0.041$), administering catecholamines before 36 h of management (AUC = 0.70, 95% CI [0.53–0.87], $p=0.010$), mechanical ventilation for more than 108 h (AUC = 0.92, 95% CI [0.86–0.99], $p<103$), administering sedation for more than 84 h (AUC = 0.82, 95% CI [0.71–0.93], $p<103$), and extubation after 6 days of management (AUC = 0.84, 95% CI [0.65–1], $p=0.024$) were associated with high risk of nosocomial infection.
**Conclusions:** Identifying the main risk factors of nosocomial infections remains crucial to develop preventive strategies to improve patients' outcomes and reduce healthcare costs.

### Respiratory variations of red blood cell velocities in the sublingual microcirculation of healthy volunteers

J. D. Romano[1], M. Mugno[2], A. Dubin[2], X. Monnet[3], V. Edul[1]
[1]División Terapia Intensiva, Hospital Juan A. Fernández, Ciudad Autónoma de Buenos Aires, Argentina; [2]Servicio de Terapia Intensiva, Sanatorio Otamendi y Miroli, Buenos Aires, Argentina; [3]Médecine Intensive - Réanimation, Inserm UMR S_999, fhu Sepsis, Groupe de Recherche Carmas, Bicetre Hospital AP-HP Université Paris-Saclay DMU Correve, Le Kremlin-Bicêtre, France
**Correspondence:** V. Edul
***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001290

**Introduction:** In clinical practice, changes in stroke volume during the respiratory cycle are used to estimate ventricular preload (1). Although capillary blood flow is laminar, the effects of respiratory changes on pulsatile systemic flow might modify red blood cell velocity (RBCv) in microcirculation. Whether these changes affect microcirculatory flow is unknown.
**Objectives:** To characterize the respiratory changes of sublingual RBCv in healthy volunteers throughout the respiratory cycle.
**Methods: Population:** 34 healthy volunteers were included.
**Design:** Cross-sectional study.
**Procedure:** Healthy volunteers were studied after 20 min of semirecumbent position. Age, body mass index (BMI), arterial blood pressure (ABP), heart rate (HR), respiratory rate (RR), pulse oximetry (SpO2), capillary refill time (CRT) and derived perfusion index (PI) were registered.
**Microcirculatory measurements:** Sublingual microcirculatory network was evaluated by means of an incident dark field illumination (IDF) imaging device. Each volunteer underwent 3 sublingual microcirculatory videos at baseline. In addition, 2 further videos were acquired at voluntary inspiratory and expiratory periods of apnea of 20 s. We performed a software-assisted analysis (AVA 3.2, Microvision Medical) to determine total vessel density (TVD), proportion of perfused vessels (PPV), perfused vascular density (PVD), microvascular flow index (MFI) and RBCv. Quantitative RBCv was measured using space–time diagrams in 10 capillaries per video.
**Statistical Analysis:** Differences in the microcirculatory variables between inspiration and expiration were explored by paired *t*-test. A P value < 0.05 was considered statistically significant.
**Results:** Healthy volunteers were 35 ± 9 years old and 60% were male. There were no differences in TVD, PVD, and PPV but RBCv was significantly higher in inspiration than in expiration: 1620 (170) vs. 1487 (134) µm/sec (p-value = 0.0008), respectively (Figure 1).
**Conclusions:** For the first time, we demonstrated the presence of respiratory changes in the sublingual RBCv of healthy volunteers. These changes are probably secondary to modifications in systemic flow induced by ventilation. Microcirculatory flow, though laminar, can reflect changes in systemic flow during the respiratory cycle.

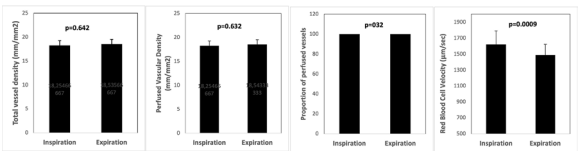

**Fig. (abstract 001290)** Differences in microvascular variables between inspiration and expiration

***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001291

**Introduction:** Acute myocardial infarction-related cardiogenic shock (AMI-CS) is associated with severe organ hypoperfusion, leading to the release of several mediators in the blood. Dipeptidyl peptidase 3 (DPP3) is a cytoplasmic metallopeptidase released in the bloodstream during an acute ischemic tissue injury. Circulating DPP3 cleaves various bioactive peptides, including angiotensin II (AngII)1. The degradation of AngII worsens the circulatory failure, hence providing a key pathological role of DPP3 in shock2. Therefore, DPP3 could be considered as a marker of hypoperfusion and a mediator of circulatory failure. However, it remains unknown how organs contribute differently to its systemic concentration.
**Objectives:** To measure DPP3 released in the bloodstream by different organs and assess each organ contribution in an experimental swine model of AMI-CS3.
**Methods:** Embolization particles were injected in the left main coronary artery to induce AMI-CS. After shock induction VA-ECMO was used as resuscitation strategy for a total of 9.5 h. Blood samples were collected from different organ vessels to quantify DPP3 release during the experiment. We collected the venous drainage from portal, sushepatic and renal veins, as well as coronary and jugular sinuses. We estimated the release of DPP3 by measuring the ΔDPP3 activity, calculated as the veno-arterial difference for each organ. Mixed venous oxygen saturation (SvO2) and veno-arterial CO2 pressure gradient (P(v-a) CO2) were extracted from a pulmonary artery catheter.
**Results:** Preliminary results were gathered from the first three animals. After induction, CS was characterized by a drop in cardiac output (−48% from 6.37 ± 0.57 L/min at baseline to 3.30 ± 0 L/min at 120 min of ischemia), a decrease in mean arterial pressure below 60 mmHg (from 75 ± 4 mmHg at baseline to 53 ± 0.7 mmHg), SvO2(from 63 ± 6% at baseline to 43 ± 6%) and P(v-a)CO2 (from 8 ± 2 mmHg at baseline to 13 ± 5 mmHg). Support with VA-ECMO restored blood pressure to ≥ 60 mmHg and tissular perfusion marker (SvO2 and P(v-a)CO2) (Figure 1). Circulating DPP3 increased during CS induction and resuscitation, thus showing an overall release of DPP3 during AMI-CS (+45% from 301 ± 104 U/L at baseline to 435 ± 152 U/L at the end of resuscitation). All the organs contributed differently to the liberation of DPP3 during and after the AMI induction. Among them, myocardium and brain seemed to be the organs the most involved in the DPP3 release, as measured by the ΔDPP3 activity (Figure 2).
**Conclusions:** For the first time in an experimental cardiogenic shock model, we show the release of DPP3 with a different contribution of each organ to the circulating DPP3 concentration. The explanation to the greater contribution of the heart and the brain might be sought in the severity of their perfusion impairment, hence the more a tissue suffers the more the DPP3 is released.

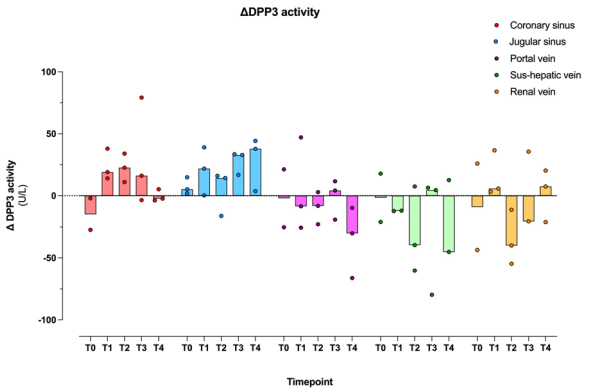

**Fig. 2 (abstract 001291)** Organs ΔDPP3 activity. ΔDPP3 activity was calculated as the difference between the venous blood and closest arterial blood of each organ. T0: baseline; T1: after 2 h of ischemia; T2: after 90′ of resuscitation; T3: after 5.5 h of resuscitation; T4: after 9.5 h of resuscitation

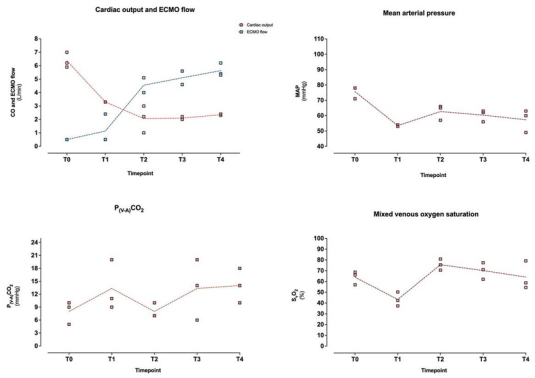

**Fig. 1 (abstract 001291)** Systemic hemodynamics and tissular perfusion markers. CO: cardiac output; ECMO: extracorporeal membrane oxygenation; MAP: mean arterial pressure; P(v-a)CO2: veno-arterial CO2 pressure gradient; SvO2: mixed venous oxygen saturation; T0: baseline; T1: after 2 h of ischemia; T2: after 90′ of resuscitation; T3: after 5.5 h of resuscitation; T4: after 9.5 h of resuscitation

**Introduction:** Recovery and rehabilitation are important stages following critical illness. Many patients experience post-intensive care syndrome and may benefit from additional input, made available through an ICU follow-up clinic. A survey in 2021 briefly described the impact of the COVID-19 pandemic on ICU follow-up services [1], but the follow-up provided to survivors of COVID-19 critical illness has not yet been described.
**Objectives:** The objective of this study is to evaluate the provision of follow-up services for adults in the UK who survived COVID-19 critical illness.
**Methods:** An online electronic survey was sent to ICU clinicians at all UK National Health Service (NHS) hospitals with an intensive care or high dependency unit. The survey was shared via mailing lists and social media. Non-responding sites were contacted directly. Once the a priori response rate of 70% was reached, the survey was closed.
**Results:** The survey ran from April to November 2023 and 174 of 242 (71.9%) NHS hospitals responded. An ICU follow-up service that survivors of COVID-19 critical illness could access was available in 80.5% (140/174) of UK hospitals. An existing follow-up service was in place in 64.4% (112/174) of hospitals prior to the COVID-19 pandemic.
Patients were usually first contacted by ICU follow-up teams within three months of hospital discharge (82.9%), and their initial clinic visit was most commonly between two and three months after hospital discharge (69.3%). The characteristics determining whether a patient was invited to ICU follow-up clinic varied between sites; the most common trigger for an invitation was referral by a clinician (36.4%), but 26.4% of hospitals invited all survivors of COVID-19 critical illness.
In 90% (126/140) of hospitals, the ICU follow-up service employed a multi-disciplinary team. The professions most commonly present in ICU follow-up clinics were nurses (89.3%), ICU doctors (79.3%), physiotherapists (62.9%) and psychologists (42.1%).
Respondents reported that COVID-19 pandemic restrictions forced their ICU follow-up clinics to adapt by introducing virtual and telephone consultations, which they found improved clinic attendance and improved equity of access to the clinic. Access to funding was a key determinant on whether follow-up services could be offered.
**Conclusions:** There was an expansion in the number of ICU follow-up clinics and the professions involved in delivering post-ICU care. Despite national guidance, there continues to be variation in the provision of ICU follow-up across the UK, due to funding restraints and where ICU follow-up services apply a more personalised approach. Future research should investigate the impact of online or hybrid models on equity of access to follow-up services, patient recovery, and level of patient retention compared to in-person, hospital-based interventions.

**Introduction:** The rapid response system (RRS) is associated with a reduction in in-hospital mortality. This study aimed to determine the characteristics and outcomes of patients transferred to the intensive care unit (ICU) by a rapid response team (RRT).
**Methods:** This retrospective, multicenter cohort study included patients from nine hospitals in South Korea. Adult patients who were admitted to the general ward (GW) and required RRS activation were included. Patients with do-not-resuscitate (DNR) orders and without lactate level or Sequential Organ Failure Assessment (SOFA) score were excluded.
**Results:** A total of 8,228 patients were enrolled, and 3,379 were transferred to the ICU. The most common reasons for RRT activation were respiratory distress, sepsis and septic shock. The number of patients who underwent interventions, the length of hospital stay, 28-day mortality, and in-hospital mortality were higher in the ICU group than in the GW group. Factors that could affect both 28-day and in-hospital mortality included the severity score, low PaO2/FiO2 ratio, higher lactate and C-reactive protein (CRP) levels, and hospitalization time prior to RRT activation.
**Conclusions:** ICU transfer after RRT activation does not significantly affect patient outcomes, highlighting the need for more individualized patient assessments to better individualize ICU transfer and related interventions.

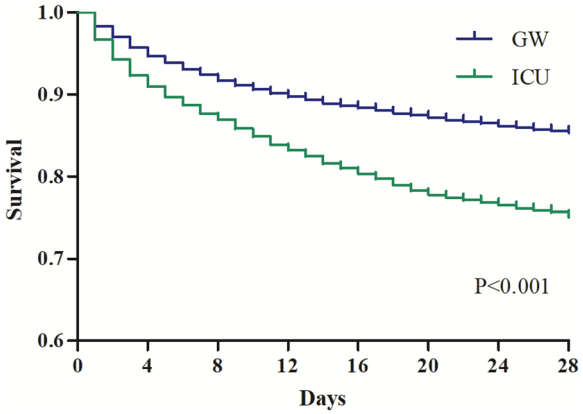

**Fig. (abstract 001294)** Twenty-eight-day mortality after RRT activation

**Introduction:** Infections pose a significant challenge in clinical settings, often leading to Intensive Care Unit (ICU) admission. Studies often focus on sepsis, and less attention is given to the focus of infection. Understanding the association between infection focus and clinical severity can help guide prophylactic measures and patient management, improving their outcomes.
**Objectives:** To assess the correlation between the type and site of infection in patients with sepsis admitted to the ICU, in mortality, length of stay, and organ dysfunction.
**Methods:** This is a retrospective, observational, and cohort analysis conducted in the ICU at Hospital de Vila Franca de Xira, Portugal. All data were retrieved from the ICU database (BICU® care). All adult inpatients admitted between 1-1-2019 and 31-12-2023, with a diagnosis of sepsis or septic shock and a community-acquired infection, were included. Patients were categorized according to the primary site of infection. Clinical and demographic data were collected including the SAPS II score. The primary outcomes assessed were hospital and ICU mortality, as well as the need for organ support therapy (renal replacement therapy, and invasive mechanical ventilation), the impact of septic shock, and bacteremia.
**Results:** A total of 888 patients were included, 58.1% male and a mean average age of 69.1 ± 12.9 years. Almost 3/4 of the patients (73.4%) had a medical site of infection. The most prevalent infections (with a sample of $N > 100$ patients) were peritonitis ($N = 201$), pneumonia ($N = 232$), pyelonephritis ($N = 125$), intra-abdominal ($N = 139$), and skin and skin structures ($N = 64$). About 40.3% of all patients had septic shock and 14% had secondary bacteremia. Its presence was associated with septic shock (OR 1.7, 95% CI 1.2–2.5), especially in patients with pyelonephritis (OR 4.9 95% CI 1.7–14.5), but not mortality (OR 0.8, 95% CI 0.5–1.1). The presence of septic shock was more common in patients with peritonitis or intra-abdominal infections (roughly 50%) and less common in pneumonia (23.3%). Septic shock increased the odds of dying (OR 3.5, 95% CI 2.6–4.6), and this was mostly noted in patients with Intra-abdominal infections (OR 6.4, 95% CI 2.5–16.8). Renal replacement therapy and invasive mechanical ventilation were commonly used especially in patients with shock (37.2% vs. 13.2% and 48.9% vs. 26.8%, respectively). Patients with pneumonia and peritonitis more often needed invasive organ support.
According to the SAPS II score, the standardized mortality rate was higher in patients with peritonitis (0.95) and pneumonia (0.9), much higher than in the general population (0.78).
**Conclusions:** Sepsis is common in the ICU. The type and focus of infection seemed to have a strong influence on clinical severity, the need for invasive organ support therapy, the impact of septic shock, and mortality. In our study, pneumonia and peritonitis had the largest impact.

**Correspondence:** C. Costa
***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001297

**Introduction:** Pelvic injuries represent a serious and potentially deathly condition in any age. Elderly patients (> 65 y old) represent an especially fragile population, with greater morbidity and mortality compared to younger patients.
**Objectives:** To describe pelvic trauma (PT) in critically ill elderly patients and to evaluate the impact of advanced age on the outcome.
**Methods:** This is a retrospective, single-centre study of all patients with PT admitted to an adult ICU of a tertiary university hospital from January 2020 to December 2023. Besides demographic data, type of trauma, severity scores, treatment options, ICU and hospital length of stay (LOS) and mortalities were collected. The statistical analysis was done with SPSS.
**Results:** Twenty-two (19.6%) of 112 patients with PT were elderly, mostly male (68.2%) with median age of 72.5 y (IQR 68.75–80). The mechanism of trauma was significantly different between younger and elderly ($p < 0.001$), with falls being the most common mechanism in this group (54.5 vs 37.8%).
Although not statistically significant, elderly presented more frequently a Shock Index ≥ 0.9 (54.5 vs 48.9%; $p = 0.634$), an arterial pH < 7.35 (40.9 vs 35%; $p = 0.326$) and a serum lactate ≥ 2 mmol/l (63.6 vs 56.7%; $p = 0.553$). Median SAPS II (48.5 vs 22; $p < 0.001$), APACHE II (18 vs 12; $p < 0.001$) scores were significantly higher in the elderly. An Injury Severity Score ≥ 15 was more frequently found in the elderly (81.8 vs 72.2%; $p = 0.357$).
In this population, the most common type of fracture according to the Young Burgees classification was lateral compression (81.8 vs 75.6%), followed by antero-posterior compression (9.1 vs 15.6%) and vertical shear (9.1 vs 5.6%) ($p = 0638$). In the elderly, most PT were grade I of WSES classification (54.5%) followed by grade II (27.3%) and grade IV (13.6%) without significant differences compared to younger patients ($p = 0.292$).
Non-operative management (NOM) was more frequently performed in the elderly (72.7 vs 61.1%) but the difference did not reach statistical significance ($p = 0.311$). Definitive surgical treatment (DST) was performed in 35% of all PT cases: 45% in the elderly and 50% in the younger group. Time to DST was significantly different between two groups: early (< 48 h) DST was more frequent in the elderly (50% vs 6.7%; $p = 0.002$). Elderly presented a significantly shorter median ICU LOS (2 vs 6.5 days; $p = 0.048$) but a significantly longer hospital LOS (30 vs 20.5 days; $p = 0.039$). Overall mortality rate was low (4.5% in ICU and 11% in hospital) and no elderly patient died.

**Conclusions:** Elderly critically ill patients with PT presented a more severe condition on admission. The most frequent type of PT was lateral compression and grade I of WSES. NOM is more frequent in the elderly but when DST is performed, it is usually done earlier than in young people. Although not impacting on mortality, it is associated with shorter ICU LOS but longer hospital LOS.

***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001298

**Introduction:** Chloralose poisoning is a frequent issue in our country's intensive care units. Its accessibility makes it one of the most common used substance for suicide among pesticides. Understanding its mechanism of action is crucial for optimal management.
**Objectives:** Our study aimed to describe epidemiological, clinical, and evolutionary characteristics of patients admitted to the intensive care unit for acute chloralose poisoning.
**Methods:** It was a retrospective, observational study conducted over a period of thirteen years, from January 2011 to December 2023. Included patients were those admitted to the department of critical of toxicology with a confirmed diagnosis of chloralose intoxication based on positive toxicological findings. Patients under 14 years old and cases of polydrug intoxication were excluded.
**Results:** Eight hundred and sixty six patients were eligible, with a mean age of 26 ± 17 years and a sex ratio of 0.53. A low socioeconomic status was noted in 360 cases (41.6%). The main comorbidities were hypertension in 40 patients (4.6%) and diabetes in 46 patients (5.3%). Two hundred and thirty-two patients (26.8%) had psychiatric history, with depressive syndrome in 98 cases (11.8%). Two hundred and seventy-nine (32.2%) patients had a history of suicide, with chloralose in 205 (23.7%). The median duration of recurrence was 240 days ± 360. The circumstances of intoxication were attempted suicide in 830 cases (96.5%), chemical submission in 18 cases (2.16%) and accidental in 12 cases (8.6%) Patients arrived at the emergency department by their own means in 58% of cases. The median assumed ingested dose was 3 g ± 3. 822 (95.4%) patients were comatose with a median Glasgow Coma Scale score of 6 ± 3. Out of coma, the main symptoms were tremors in all cases, hypersalivation (95.4%). Orotracheal intubation was performed with a median delay of 3.5 h ± 3 for any patient presenting with coma; myoclonus was managed with propofol in 641 cases (74%) and benzodiazepine in 391 (45%) All patients had a positive toxicological finding in urine, and 445 (51.4%) in gastric fluid. The most frequent complication was aspiration pneumonia in 279 patients (32.2%). The mean duration of mechanical ventilation was 16 h ± 12. The majority of patients ($n = 863$) evolve favorably with a mortality rate of 0.3%.
**Conclusions:** Chloralose poisoning remains a challenge in intensive care, with specific epidemiological, clinical, and prognostic characteristics. Improved knowledge of these aspects could help enhance patient management and reduce associated complications.

### What do we know about carbamazepine poisoning? An epidemiological study

N. Brahmi[1], A. Smiri[1], M. Kharrat[2], A. Ben Jazia[1], M. Jemii[1], H. Ben Ghezala[1]
[1]Critical Care Unit Mahmoud Yaacoub Emergency Medical Center, University of Tunis El Manar, Rommana, Tunisia; [2]Intensive Care Unit, Regional Hospital Zaghouan, Faculty of Medicine of Tunis, University Tunis El Manar, Tunis, Tunisia, Tunis, Tunisia
**Correspondence:** H. Ben Ghezala
***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001299

**Introduction:** Carbamazepine (CBZ) is a widely prescribed treatment for neurological and psychiatric disorders. Its misuse can cause acute poisoning requiring intensive care unit management.
**Objectives:** This study aimed to carefully examine the epidemiological characteristics of this poisoning.
**Methods:** This was a retrospective, observational study conducted over a fourteen-year period, from January 2010 to December 2023. All symptomatic patients with positive toxicology screening were included in the study.
**Results:** A total of 408 patients were included, with a mean age of 29 ± 12 years and a sex ratio of 0.58. The main comorbidity was epilepsy ($n = 55$; 13.5%). Two hundred and fifty-two patients had psychiatric disorders (61.8%), including a history of suicide attempts in 117 cases (28%). Two hundred and fifty-three patients (62%) were on long-term treatment, for a median duration of 5 years. The mean consultation delay was 6.3 h ± 4, with an average ingested dose assumed to be 5 g ± 4.2 based on interrogation. An association with another molecule was reported in 175 cases (42.9%), mostly with benzodiazepines ($n = 63$, 15.4%). Intoxication was voluntary for 396 patients (97.1%) and due to a therapeutic error in other cases. Neurological manifestations were predominant. Anticholinergic toxidrome was present in 112 patients (27.5%). Deep coma was noted in 168 patients (41%), conscious failure in 202 (49%) with a mean Glasgow Coma Scale score at 10.4 ± 3.5, agitation in 76 (18.6%), dysarthria in 20 (4.9%) and seizure in 11 (2.7%). The most frequent ECG abnormality reported was sinus tachycardia ($n = 56$, 13.7%). Laboratory findings showed hyponatremia in 127 cases (31%), a mean blood carbamazepine level of 26.70 mg/l ± 11, measured at least twice in 308 cases, with a mean decreased to 21 mg/l ± 9 after 24 h of management. Intubation with requiring mechanical ventilation was performed in 202 patients with a median mechanical ventilation duration of 48 h. The median length of stay was 3 days. Nine patients (2.2) died from ICU complications.
**Conclusions:** CBZ poisoning can be serious, leading to death in 2.2% of cases. Hyponatremia is a very common metabolic consequence. There is currently no antidote and treatment is purely symptomatic. Early and appropriate management, including careful monitoring of clinical and biological parameters, is essential to ensure a favorable outcome.

**Introduction:** Sepsis damages the endothelial glycocalyx, which is a carbohydrate-rich layer that covers the luminal capillary endothelium. In addition, capillary blood flow is significantly reduced in sepsis. However, our previous data indicates that these dysregulations are independent of each other. This pilot study aims to investigate this decoupling of glycocalyx thickness and functional capillary density and its potential relationship to changes in peripheral blood mononuclear cells (PBMCs).
**Methods:** This prospective, observational, clinical-experimental cross-sectional study was conducted in the interdisciplinary emergency department of the University Hospital Münster, Germany. Forty-nine adult patients with suspected bacterial infection or sepsis were prospectively enrolled, while 17 healthy volunteers served as controls. Hand-held, non-invasive sublingual video microscopy with a sidestream dark-field imaging device was used to estimate glycocalyx dimensions and measure functional capillary density. Blood samples for PBMC isolation were taken on enrollment and deep flow cytometric immune cell profiling was performed.
**Results:** Microvascular imaging showed reduced glycocalyx thickness and decreased capillary density during infection. Notably, the two parameters were not related to each other. Deep phenotyping revealed monocyte subpopulations up- and CD8+ naive T cells downregulated in patients with infection. Of those, several markers showed a strong correlation with either glycocalyx thickness (e.g. negative correlation of IL-8+ monocytes, mDC cells with correlation coefficient $r < -0.5$; strong positive correlation of intermediate monocytes, CD25+ mDC with $r > 0.5$) or capillary density (negative correlation of CD197+ monocytes, positive correlation of CD56+ dim CD69+) but without any meaningful overlap.
**Conclusions:** This study shows that distinct changes in immune cell phenotype coincide with the decoupling of glycocalyx properties and capillary density. These findings can serve as a basis for further mechanistic studies.

**Topic:** Sepsis

***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001302

**Introduction:** Fluid resuscitation if often needed in neurocritical care patients to maintain perfusion and normovolemia, taking into account pathophysiological aspects such as tonicity, aedema and autoregulation (1). Plenty of evidence exist regarding type of fluid, goal-directed fluid therapy and assessing volume responsiveness (2). Deresuscitation begins when resuscitation has been successful and aims to obtain zero fluid balance, but the time that takes to complete that zero fluid balance remains to be determined (3).
**Objectives:** To evaluate maximum time to zero fluid balance (TmaxZFB) with duration of mechanical ventilation, ICU and hospital length of stay and mortality.
**Methods:** We conducted a prospective cohort study of neurocritical care patients admitted to an ICU in northeast Mexico, included adult patients during 2021–2022. TmaxZFB defined as the duration that took to accomplish zero fluid balance in hours. Continuous variables are described as median and interquartile range and categorical variables as frequency and percentages. To test null hypothesis, we used Mann–Whitney U test and a p value of $< 0.05$ as statistical significance.
**Results:** A total of 50 neurocritical care adult patients were included, 52% were males ($n = 26$), most frequent origin was OR 72% ($n = 36$), most common diagnosis were tumor resection 50% ($n = 25$), traumatic brain injury 24% ($n = 12$), subarachnoid hemorrhage and spontaneous brain hemorrhage 24% ($n = 24$), and stroke 2% ($n = 1$). 51% required hyperosmolar therapy, 32% were admitted with shock state requiring resuscitation with crystalloids. Two groups were evaluated according to survival (40/10), pre-ICU fluid balance median was 732 mL (IQR 223–1683) vs 510 mL (IQR −583.7–768.7) in no survivors group ($p = 0.053$), first 24 h fluid balance in survival group was 370 mL (IQR −365.7–1002) vs 547 mL (IQR −911.2–1172.7) in no survivors ($p = 0.56$) time to positive fluid balance in survival group was 8 h (IQR 7–16.5) vs 14 h (IQR 8–24) in no survivors ($p = 0.17$). Time to zero fluid balance in survival group was 16 h (8.2–25.5) vs 18.5 h (IQR 4–54) in no survivors ($p = 0.65$), mechanical ventilation days were 1.5 (IQR 1–4) vs 5 days (IQR 2.7–12.2) in no survivors (Graph 1) ($p = 0.012$), ICU length of stay 3.5 days (IQR 2–6) vs 5.5 days (IQR 3–8.2) in no survivors ($p = 0.25$), hospital length of stay 15 days (IQR 9.2–25.5) vs 11 days (IQR 3–14.5) in no survivors ($p = 0.02$).
**Conclusions:** There is a U-shaped relationship with fluid administration in which under resuscitation is associated with mortality and over administration of fluid therapy and associated with increased complications. In our study, there is a statistical difference between both groups regarding increased length of mechanical ventilation and hospital length of stay; however, TmaxZFB was not different between both the groups. Deresuscitation took longer time to be accomplished in no survivors group, although no statistical difference was found.

***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001303

**Introduction:** The microbiological diagnosis of lower respiratory tract-associated infections is challenging due to the low sensitivity and prolonged wait times to conventional cultures' results. Biofire Filmarray Pneumonia Panel Plus (BFPP) can improve diagnosis performance (1), allowing for shorter times to culture positivity and faster directed therapy.
**Objectives:** To assess the impact of Biofire Filmarray Pneumonia Panel Plus (BFPP) and bronchoalveolar lavage (BAL) cultures in time from sample to directed antibiotic therapy in patients with ventilator-associated pneumonia (VAP), nosocomial pneumonia (NP) that requires mechanical ventilation or community-acquired pneumonia (CAP) with risk factors for treatment failure (2).
**Methods:** This is an observational prospective study. Adult patients admitted to the intensive care unit between January 2022 and May 2023 and diagnosed with VAP, NP or CAP and any of the following risk factors for antibiotic failure were selected: risk factors for infection for multidrug-resistant microorganisms (MDRO) such as previous colonization by MDRO, antibiotic treatment within the previous 90 days, previous admission in areas with high prevalence of MDRM or risk factors related to the patient (immunosuppression on septic shock).
Bronchoalveolar lavage samples were processed both with BFPP and conventional cultures. BFPP was available from 8 to 20 h Monday to Friday. Conventional cultures were processed and interpreted Monday to Sunday from 8 to 22 h. Positive results were notified via direct call and uploaded to the clinical report systems.
The population is described using frequency and percentage, mean and standard deviation (SD) or median and interquartile range (IQR) as appropriate. Differences in time to directed therapy were assessed using Student's T test for unpaired data. Statistical significance was set at $p < 0.05$.
The project received approval by the ethics committee.
**Results:** Sixty patients that met inclusion criteria were identified. 36 (60%) were male. Median age was 59 (IQR 50–66) years old. Median APACHE was 20 (IQR 11–28). The most frequent comorbidities were pulmonary disease (16–26.7%), diabetes mellitus (12–20%) and chronic kidney disease (11.7%). 32 patients had risk factors for MDRO, 14 were in septic shock at diagnosis and 30 were immunosuppressed. Median duration of mechanical ventilation was 35 (18–55) days. The most common lower respiratory tract infection diagnosis was VAP (44, 73.3%), followed by CAP (11, 18.3%) and NP (5, 8.3%). Three (5%) received inadequate empirical antibiotic treatment that required escalation after microbiological results.
BFPP led to therapeutic changes in 21 patients. Definitive culture results led to 9 further treatment modifications (Table 1).
Average time from sample obtention to antibiotic modification was < 1 day (mean 4, 8 h SD 9.6 h) for BFPP and over four days (mean 105.6 h, SD 79.2 h) for conventional cultures ($p < 0.001$).
**Conclusions:** BFPP may lead to faster directed antibiotic therapy and decreased inadequate empirical therapy in patients with lower respiratory tract bacterial infections and risk factors for treatment failure.

**Table 1 (abstract 001303)** Modifications of antibiotic treatment according to BFPP and culture results

| | BFPP (n=60) | | | BAL culture after BFPP (n=60) | | |
|---|---|---|---|---|---|---|
| | Negative (36 – 60%) | Positive (24 -40%) | Total | Negative (39 – 65%) | Positive (21 -35%) | Total |
| Escalation | 1 | 3 | 4 | 0 | 0 | 0 |
| De-escalation | 3 | 7 | 10 | 2 | 4 | 6 |
| Stop | 5 | 2 | 7 | 2 | 1 | 3 |
| Total | 9 | 12 | 21 | 4 | 5 | 9 |

***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001305

**Introduction:** The diagnosis of lower respiratory tract associated infections is challenging due to the low sensitivity and prolonged wait times to conventional cultures' results. Biofire Filmarray Pneumonia Panel Plus (BFPP) can improve diagnosis performance (1), allowing for shorter times to culture positivity and faster directed therapy.
**Objectives:** To assess differences in agreement and time to validation between BFPP and conventional bronchoalveolar lavage (BAL) cultures (including antibiogram) in patients with ventilator-associated pneumonia (VAP), nosocomial pneumonia (NP) that requires mechanical ventilation or community acquired pneumonia (CAP) with risk factors for treatment failure (2).
**Methods:** This is an observational prospective study including adult patients admitted to the intensive care unit and diagnosed with VAP, NP or CAP and risk factors for antibiotic failure.
Bronchoalveolar lavage samples were processed both with BFPP and conventional cultures. BFPP was available from 8 to 20 h Monday to Friday. Conventional cultures were processed and interpreted Monday to Sunday from 8 to 22 h.
Agreement between tests was calculated using Cohen's kappa test, both for all results and later exclusively for the 16 bacterial targets contained in BFPP. Differences in time to positivity were calculated using Wilcoxon signed-rank test. Statistical significance was established in $p < 0.05$.
The project received approval by the ethics committee.
**Results:** Sixty patients that met inclusion criteria were identified. 36 (60%) were male. Median age was 59 (IQR 50–66) years old. Median APACHE was 20 (IQR 11–28). The most frequent comorbidities were pulmonary disease (16–26.7%), diabetes mellitus (12–20%) and chronic kidney disease (11.7%). 32 patients had risk factors for MDRO, 14 were in septic shock at diagnosis and 30 were immunosuppressed. Median duration of mechanical ventilation was 35 (18–55) days.
The most common lower respiratory tract infection diagnosis was VAP (44, 73.3%), followed by CAP (11, 18.3%) and NP (5, 8.3%).
There was fair agreement between tests (68.3%, $k = 0.326$ SE = 0.128 $p = 0.0055$).
Six of the 11 cases with positive BFPP and negative cultures were due to positivity of viral targets. Regarding positive BAL and negative BFPP, disagreement was caused by isolation of enterococci in 2 cases, plasma coagulase-negative staphylococci in 3 cases, polymicrobial sample contamination in 2 and *Chryseobacterium indologenes* in one. When only comparing molecular targets contained by the test,

agreement was substantial (85%, $k = 0.603$ $p < 0.001$). Test results are summarized in Table 1.
Median time to validation was 2.5 h (2–10) for BFPP and 43.3 h (40–48.3) to BAL cultures, including antibiogram ($p < 0.001$).
**Conclusions:** BFPP leads to a faster microbiological diagnosis, with fair to substantial agreement with conventional cultures.

**Table 1 (abstract 001305)** Positive and negative test results (conventional cultures vs. Biofire® Filmarray® Pneumonia Panel Plus)

| | Negative BAL | Positive BAL | Total FA |
|---|---|---|---|
| Negative BFPP (%) | 28 (71.8) | 8 (38.1) | 36 |
| Positive BFPP (%) | 11 (38.3) | 13 (61.9) | 24 |
| Total BAL | 39 | 21 | 60 |

### Investigating muscle and bone loss in the intensive care unit with opportunistic computed tomography imaging

A. C. Smith[1], K. N. Bott[1], B. M. Hisey[2], B. E. Matheson[1], C. H. Lee[3], R. E. Walker[1], K. J. Solverson[2], C. J. Grant[2], S. K. Boyd[1], C. J. Doig[2], S. L. Manske[1]

***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001310

**Introduction:** Critical care patients are susceptible to muscle weakness and bone loss. This can lead to fractures and long-term physical impairment. Muscle biopsies indicate that muscle weakness may be associated with muscle atrophy and muscle fatty infiltration. However, it is unclear how these mechanisms contribute to muscle weakness in critical care patients. Bone loss among critical care patients has been scarcely investigated. Novel internal calibration methods (1,2) have enabled the repurposing of computed tomography (CT) images acquired in the intensive care unit (ICU) to evaluate muscle density and bone mineral density (BMD).
**Objectives:** 1) Measure changes in muscle cross-sectional area (CSA), muscle density, and BMD over the course of critical illness using clinically acquired CT images. 2) Determine risk factors associated with muscle loss.
**Methods:** We retrospectively acquired abdominal CT scans of ICU trauma and sepsis patients. Patients were included if they had a CT scan within 48 h of ICU admission (baseline) and a second CT scan taken > 3 days later (follow-up). We assessed mean psoas muscle CSA ($cm^2$) by segmenting the psoas muscle at L3 using an automated algorithm (3) with manual correction. For a subsample of patients with non-contrast enhanced scans, we measured psoas muscle density using an internal calibration approach (2). We assessed femur BMD for a subsample of patients with > 14 days between their baseline and follow-up scans using a machine learning algorithm and internal calibration approach (1). We acquired patient information using electronic medical records.
**Results:** Critical care patients ($n = 164$) experienced an 8% reduction in psoas muscle CSA (1.2 $cm^2$, IQR = 0.1, 2.3) over a median 9 days in the ICU. This represents a median muscle CSA loss of just under 1% per day. Patients ($n = 23$) experienced a 0.4% reduction in psoas muscle density ($p < 0.05$). Patients in the bone analysis subsample ($n = 14$) had no difference between baseline and follow-up femur BMD ($p = 0.46$). Patients with greater muscle at baseline or greater time in the ICU experienced more profound muscle CSA loss ($p < 0.001$). Rapid muscle CSA loss was associated with ICU mortality in sepsis patients ($p < 0.05$). Lesser muscle CSA at follow-up was associated with female sex, sepsis, greater time in the ICU, and greater illness severity ($p < 0.05$).
**Conclusions:** Muscle loss in the ICU involves a reduction in muscle CSA and density. Patients with the most rapid muscle CSA loss differed from patients with the lowest follow-up muscle CSA. Future work is necessary to determine how muscle loss and CSA affect physical function post-ICU. As bedrest studies have observed BMD loss in 7–14 days (4,5), we were surprised that BMD loss was not observed in this study. This may indicate that our analysis is not sufficiently sensitive for clinically acquired CT images. While future work is needed, opportunistic CT imaging is a promising modality for clinical and research investigations of musculoskeletal changes in the ICU.

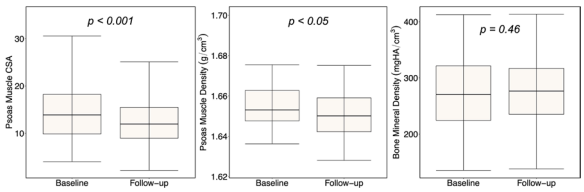

**Fig. (abstract 001310)** Box and whisker plots comparing A) psoas CSA ($n = 164$), B) psoas muscle density (g/cm^3) ($n = 23$), and C) BMD (mgHA/cm^3) ($n = 14$) at baseline and follow-up. The box represents the interquartile range. The bottom of the box is the 1st quartile, the line in the middle of the box is the 2nd quartile or the median, and the top of the box is the 3rd quartile

### A multi-center cohort study of Esomeprazole versus Omeprazole prophylaxis in critically ill patients at high risk for stress ulceration

K. Al Sulaiman[1], R. Almutairi[2], R. Alarifi[3], R. Alajmi[3], R. Alhussainan[3], S. Alkathiri[3], K. V. Ramesh[4]

**Correspondence:** K. Al Sulaiman
***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001311

**Introduction:**
Stress ulceration can be defined as extensive superficial erosions, which mainly affect the fundus and body of the stomach. Gastrointestinal bleeding (GIB) is the most frequent sign of stress ulcers, and GIB in critically ill patients leads to a higher fatality rate. Stress ulcer prophylaxis is the standard of care to prevent stress ulcer-related bleeding in critically ill patients at high-risk (e.g., mechanical ventilation and coagulopathy). Proton pump inhibitors (PPIs) are superior to other agents in preventing GI bleeding. There is a lack of evidence of superiority among the PPI agents; therefore, we aimed to evaluate the effectiveness and safety between different PPI agents (i.e., Esomeprazole and Omeprazole) as SUP in critically ill patients
**Methods:**
This is a multicenter retrospective cohort study of critically ill adult patients admitted to the ICUs at four centers between January 1, 2018, and December 31, 2021. Eligible patients were categorized into two sub-cohorts based on the type of PPI agent as SUP (Esomeprazole versus Omeprazole). The primary outcome was the incidence of

confirmed GI bleeding, while mortality, MV duration, ICU/hospital LOS, and complications during ICU stay were considered secondary outcomes. Propensity score (PS) matching was employed based on the patient's age, body mass index (BMI), APACHE II score, baseline INR, baseline total bilirubin, MV status within 24 h of ICU admission, history of bleeding within six months prior to ICU admission, liver disease as comorbid conditions and the dosing of PPI as SUP prophylaxis. Multivariable logistic, Cox proportional hazards, and negative binomial regression analysis were utilized as appropriate

**Results:**

We screened 10,507 critically ill patients; 5566 patients were eligible. After PS matching (1:3 ratio) based on the predefined criteria, the demographic variables (e.g., Age, BMI), severity scores (e.g., APACHE II, SOFA), MV status, and coagulation profile at admission were comparable between the groups. The incidence of confirmed GI was higher in patients who received Omeprazole than Esomeprazole as SUP (7.3% versus 2.3%; aOR: 3.34, 95% CI: 1.99, 5.57; $p=0.01$). In addition, the MV duration and ICU LOS were significantly longer in the Omeprazole group versus esomeprazole (beta coefficient: 0.19, 95% CI: 0.01, 0.36; $p=0.04$, and beta coefficient: 0.48, 95% CI: 0.38, 0.58; $p=0.01$). Patients who received Omeprazole as SUP had a higher 30-day and in-hospital mortality compared with Esomeprazole (HR: 1.49, 95% CI: 1.27, 1.75; $p=0.01$, and HR: 1.75, 95% CI: 1.51, 2.03; $p=0.01$, respectively)

**Conclusions:**

Omeprazole use as SUP in critically ill was associated with a higher incidence of confirmed GI bleeding with increased MV duration and length of stay. Moreover, Omeprazole was associated with higher mortality rates. Further randomized control studies are needed to confirm these findings

**Introduction:** Mortality of critically ill cancer patients admitted to intensive care units has drastically reduced over the last decades (1). Characteristics and outcomes of patients with haematological malignancies needing treatment in a university hospital's tertiary intensive care units during 2018–2022 were assessed in this retrospective cohort study.

**Objectives:** To describe the population of intensive care unit (ICU) patients with haematological malignancies at Tartu University Hospital and to assess the outcomes of intensive care and risk factors for death. The primary outcome was ICU mortality, and secondary outcomes included hospital and one-year mortality.

**Methods:** All patients admitted to tertiary ICU-s at Tartu University Hospital in 2018–2022 were screened for diagnoses of any malignant haematological neoplasm (ICD codes C81-C96, D45-D47). Patients that were admitted to ICU due to complications or for the treatment of their haematological illness were included. Data were collected retrospectively from paper and electronic health records.

**Results:** 152 patients were included in the study. The main reason for ICU admission was shock ($n=57$, 37.5%), followed by respiratory failure (RF) ($n=48$, 31.6%). Median APACHE II score was 28 points. On admission day, most patients had sepsis ($n=102$, 67.1%) with 61 patients presenting with septic shock (40.1%). Vasopressor therapy was used in 66.4% of patients during the first 24 h ($n=101$). During their ICU stay, acute RF developed in 114 patients (75%), out of whom 80 (70.2% of those with RF) received invasive ventilation. Acute kidney injury (AKI) developed in 99 patients (65.1%) and renal replacement therapy was used in 43 patients (43.4% of those with AKI). Extracorporeal membrane oxygenation was used in 2 patients. In 41 patients (27.0%), a decision on limitation of care was made during ICU stay. Median hospital length of stay (LOS) before ICU admission was 0 days (IQR 0–8 days) and median ICU LOS 3 days (IQR 1–9 days). Readmission to ICU occurred in 10 patients (6.6%).ICU mortality was 34.2% ($n=52$), hospital mortality 41.4% ($n=63$) and one-year mortality 62.5% ($n=95$). In ICU long-stayers (LOS > 7 days; $n=42$; 27.6%), outcomes were similar. Predictors of ICU mortality are shown in Table 1.

**Table 1 (abstract 001312)** Risk factors for mortality

| | | 95% C.I. for OR | | |
|---|---|---|---|---|
| | OR | Lower | Upper | *P*-value |
| Use of vasopressors on admission day | 5.865 | 1.387 | 24.791 | 0.016 |
| No invasive mechanical ventilation during ICU | 3.539 | 1.154 | 10.856 | 0.027 |
| pH at admission | 0.008 | < 0.001 | 0.714 | 0.035 |
| Lactate at admission | 1.208 | 1.001 | 1.459 | 0.049 |
| SOFA on admission day | 1.477 | 1.194 | 1.826 | < 0.001 |

**Conclusions:** Shock, often caused by sepsis, is the primary reason for ICU admission in patients with haematological malignancies in our cohort. ICU admission is not a universally fatal event in this patient population, as more than one-third are still alive one year after intensive care. Our data suggests that the presence of a haematological malignancy should not in itself limit access to intensive care.

**Introduction:** Diuretics are primarily used to eliminate body water excess. To excrete water, the final mechanism of natriuretic diuretics is to increase the number of osmoles eliminated. Furosemide acts by increasing urinary sodium and chloride osmoles, while mannitol acts by adding un-physiological sugar osmoles.

**Objectives:** In this study, we investigated the differences between furosemide and mannitol on water elimination and urinary electrolytes handling.

**Methods:** The study population consisted of 37 ICU patients, with normal kidney function, prospectively treated with mannitol (1 g/kg of ideal body weight) in whom urinary electrolytes and pH were analysed by K.IN.G.® (Kidney Instant Monitoring). Urinary output, pH and sodium, potassium, chloride, and ammonium concentrations before (BASAL) and after a single-dose mannitol administration were assessed for 3 h at 30 min intervals. Urinary sodium to potassium ratio (Na/K ratio), sodium fractional and total excretion were computed. Data from 39 patients treated with a single-dose furosemide (12 ± 5 mg) reported in a previous study (Zazzeron et al., 2016) were considered for comparison.
**Results:** Time course of urinary output, sodium and chloride concentrations are shown in Figure 1. Urinary output was similar after furosemide or mannitol ($p = 0.447$). Sodium and chloride concentrations, sodium fractional and total excretion were markedly higher in patients treated with furosemide (all $p < 0.05$). Time course of potassium and ammonium concentration in the two populations were similar, with progressive increase in their excretions, likely due to pH and aldosterone effects. Indeed, urinary ammonium concentration significantly increased with decreasing urinary pH (R2 = 0.03, $p < 0.001$) and was significantly and negatively correlated with urinary Na/K ratio (R2 = 0.28, $p = 0.047$).
**Conclusions:** This study suggests that water elimination is similar after treatment with furosemide or mannitol. The main difference was found in the urinary electrolytes' modifications. In patients in whom the clinical target is water elimination rather than natriuresis, mannitol may be considered as a possible alternative to furosemide.

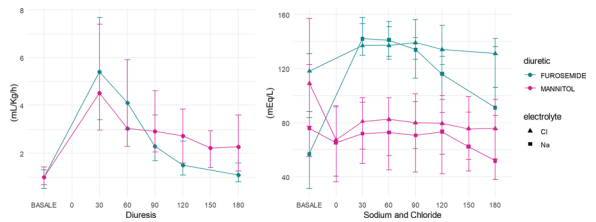

**Fig. (abstract 001313)** Time course of diuresis and urinary sodium and chloride concentration before (BASAL) and after administration of diuretic
Two-way ANOVA for repeated measures. Data are expressed as median (IQR). A $p$-value < 0.05 was considered as significant. Differences between the two populations (Furosemide vs Mannitol) are the following: Diuresis ($p = 0.447$), Sodium ($p = 0.002$), Chloride ($p < 0.001$).

***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001316

**Introduction:** Fluid therapy aims to increase intravascular volume to improve left ventricular preload and enhance cardiac output. This improves oxygen delivery to the tissues and prevents hypoperfusion. However, fluid overload can have detrimental effects at both microcirculatory and macrocirculatory level and affect the patient's outcome.
**Objectives:** This study aimed to evaluate the impact of fluid balance at 24 and 48 h on the outcome of critically ill patients.
**Methods:** This is a retrospective single-center study which included patients admitted to the Intensive Care Unit (ICU) from 2019 to 2023. Patients under 18 years old, those hospitalized for less than 24 h and chronic kidney disease patients on kidney replacement therapy were excluded. The patients were divided into four groups based on their first 24-h fluid balance (FB) quadrants (< 0 ml; 0–869 ml; 870–1855 ml; > 1856 ml). Primary endpoint was to evaluate whether a higher FB in the first 24 and 48 h after ICU admission is associated with higher hospital mortality. Secondary endpoints were to evaluate association with higher ICU mortality, days on mechanical ventilation (MV) and days in ICU and hospitalization.
**Results:** We included 2103 patients, with a median age of 66.0 (55.0–75.0) years, 62.7% being male, and a mean FB of 869 mL (0–1855). The mean APACHEII score was 20.0 (15.0–26.0). Hospital mortality in the four different 24-h FB groups was 30.6%, 36.9%, 38.3%, and 49.0%, with a 38.7% overall hospital mortality. In the four 48-h FB groups, hospital mortality was 30.9%, 33.8%, 34.2%, and 45.3%, with a 39.5% overall hospital mortality.
Higher FB in the first 24-h was associated with increased mortality ($p < 0.001$). This trend was also observed with 48-h FB ($p < 0.001$). Cox regression analysis using four different groups (separated by quartiles) revealed a significant increase in mortality in higher quartiles (except between groups 2 and 3—0–1855 mL; Graph A and B, 24 and 48 h, respectively).
In addition, an increase in FB in the first 24 h after ICU admission was associated with increased ICU mortality ($p < 0.001$), prolonged ICU stay ($p < 0.001$) and duration of MV ($p < 0.001$). However, no difference was found in the number of days hospitalized ($p = 0.104$). Similar results were observed with FB in the first 48 h, showing an increase in ICU mortality ($p < 0.001$), ICU stay ($p < 0.001$), and MV days ($p < 0.001$). No difference in the number of days hospitalized ($p = 0.232$).
**Conclusions:** In our population, higher 24 and 48 h of FB were associated with increased hospital and ICU mortality, longer ICU stay and an extended duration of MV.

***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001317

**Introduction:** Cardiac tamponade is a medical emergency, due to the accumulation of fluid in the pericardial sac that compresses the heart chambers and leads to a decrease in cardiac output. Pericardial effusions (PE) causing tamponade arise from diverse etiologies across acute and sub-acute time courses.
Management is guided by the hemodynamic impact, size, and suspected etiology. In an emergency setting, prompt recognition,

through clinical signs and echocardiography, and drainage at the bedside are critical to prevent cardiovascular collapse.
Catheter pericardiocentesis guided by ultrasound is the treatment of choice in most patients, as it allows for rapid decompression and sample collection for etiology investigation. Observational studies show that for practitioners proficient in echo-guided pericardiocentesis, the rate of major complications is 0.3–3.9%, and the rate of minor complications is 0.4–20%.
**Objectives:** We aim to quantify the prevalence of pericardial effusion and cardiac tamponade in the ICU, analyze the etiological entities, pericardiocentesis procedures, associated complications, length of stay (LOS) and mortality.
**Methods:** We report a retrospective observational study at a single-center Portuguese ICU over a period of 4 years (2020–2023), on patients with the diagnosis of pericardial effusion.
**Results:** Among the 32 patients analyzed, 62.5% ($n=20$) were men and the mean age was 60 years old. 69% ($n=22$) were transferred from the emergency room. Mean ICU and hospital LOS was 5 and 20 days, respectively.
At the time of admission, 72% ($n=23$) presented cardiac tamponade and 31% ($n=10$) were hemodynamic unstable. Ultrasound-guided pericardiocentesis was performed in 94% ($n=30$) of the cases, 7 of which, although were not tamponade, were drained due to increased volume and etiological investigation. We report only one complication of a small hemoperitoneum from a transhepatic subcostal approach.
ICU, hospital and 90-day mortality were 12.5% ($n=4$), 22% ($n=7$) and 28% ($n=9$), respectively.
Regarding etiology, 41% were neoplastic (28% related to lung cancer), 28% were idiopathic, 22% infectious, 6% auto-immune, and 3% hemodynamic (cardiac failure). In 7 patients, tamponade was the inaugural presentation that led to cancer diagnosis. We report 2 cases of viral pericarditis in COVID patients, who unfortunately passed away due to respiratory failure.
**Conclusions:** The casuistic presented reflects the epidemiology of a polyvalent ICU in a non-trauma nor cardiac surgery center. Nonetheless, medical etiologies represent important causes of PE that require a high index of suspicion and emergent management. Malignancies represent the primary cause of PE, the majority with inaugural presentation and diagnosis, followed by idiopathic and infectious causes.
We report only one mild complication associated with ultrasound guided pericardiocentesis, which has proven to be the safest technic, compared to blind drainage. The choice of cardiac puncture approach depends on the size and distribution of the effusion. Considering its best safety profile and high effectiveness, we believe this procedure should be included in point-of-care ultrasound training for critical care physicians.

*Intensive Care Medicine Experimental* 2024, **12(suppl 1):**001318

**Introduction:** Ventilator induced lung injury (VILI) is a cause of acute respiratory distress syndrome (ARDS). We hypothesized that inflammatory response and cytokine production during ARDS can be decreased by means of therapeutic hypothermia (TH) and influenced by the rewarming strategy used.
**Objectives:** To explore the effects of therapeutic hypothermia at 32 °C and two rewarming strategies applied after the induction of VILI in an animal model of severe ARDS, assessed by repeated measurements of cytokine concentration.
**Methods:**
Lung injury was induced in 16 anesthetized piglets using a two-hit lung injury model, composed by repeated lung lavages and injurious ventilation to reach an arterial oxygen partial pressure to fractional inspired oxygen ratio (PaO2/FiO2) of 200 mmHg corresponding to moderate ARDS. After lung injury, eleven piglets underwent TH reaching a core temperature of 34 and then 32 °C, with an intended constant decrease in temperature of 1 °C /hour. Five piglets were used as controls (i.e. ARDS without TH).
For rewarming to 38 °C, the TH group was then divided into two groups: 1) the quick rewarming (QR) group ($n=4$) exposed to a rewarming rate of 1 °C/hour; 2) the slow rewarming (SR) group ($n=7$) with a rewarming rate of 0.5 °C/hour. Lung mechanics, hemodynamics, gas exchange, plasma for cytokine determinations (IL-6, TNF-a) were collected after each temperature step change. Cytokine values were analyzed after their indexing using as reference level the concentration at 32 °C.
**Results:** All animals developed moderate ARDS; the TH animals were cooled to 32 °C and rewarmed to the baseline temperature 38 °C. During hypothermia, TH groups and controls were similar in cytokines levels (Figure 1). The animals increased in plasma IL-6 and TNF-a concentration during rewarming ($p<0.01$ for both). The SR group showed higher IL-6 concentrations than QR during rewarming phase ($p<0.02$; Figure 1b). No difference was detected in TNF-a after indexing.
**Conclusions:** In this model of moderate ARDS, re-warming phase was associated with a rebound increase in cytokine levels in blood plasma. The optimal rate of rewarming warrants further studies for differentiating the effect of temperature from the effects of its time course.

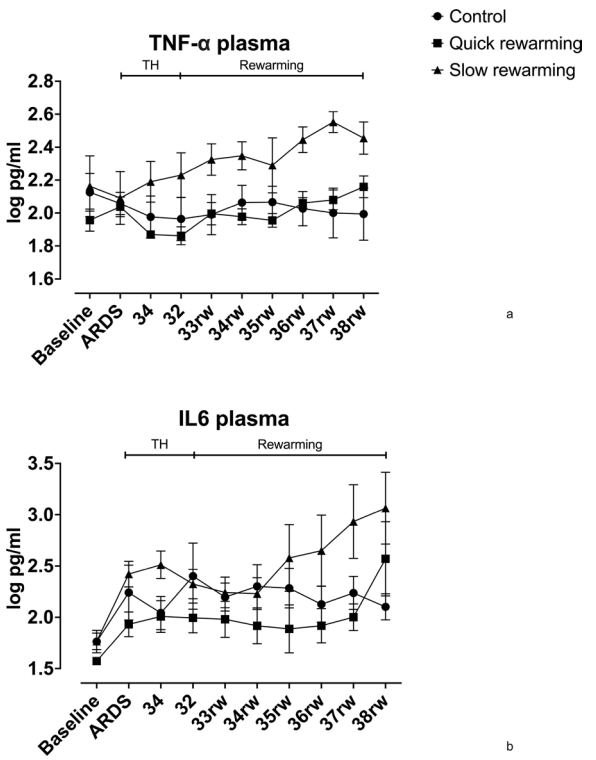

**Fig. (abstract 001318)** Cytokine concentrations during the various phases of the experiment. Numerals on the x-axis indicate the temperature in Celsius degrees. The suffix "rw" denotes temperatures reached during the rewarming phase

## Dobutamine plus levosimendan as a protective factor for the development of acute kidney injury in on-pump cardiac surgery

C. D. Del Angel Argueta[1], O. I. Aguilera Olvera[1], G. Aguirre-Gomez[1], J. A. Villalobos Silva[1]
[1]Critical Care, High Specialty Regional Hospital of Ciudad Victoria, Ciudad Victoria, Mexico
**Correspondence:** C.D. Del Angel Argueta
*Intensive Care Medicine Experimental* 2024, **12(suppl 1):**001321

**Introduction:** Acute kidney injury has an incidence of up to 40% in cardiac surgery, adding morbidity–mortality and increasing the days of hospital stay. Levosimendan, a calcium-sensitizing inotrope that improves cardiac contractility, has a vasodilatory effect and is cardioprotective against ischemia due to reperfusion, among others. On the other hand, despite a wide range of inotropic agents available, the most appropriate agent to prevent postoperative complications such as acute kidney injury or low output syndrome is still unknown.

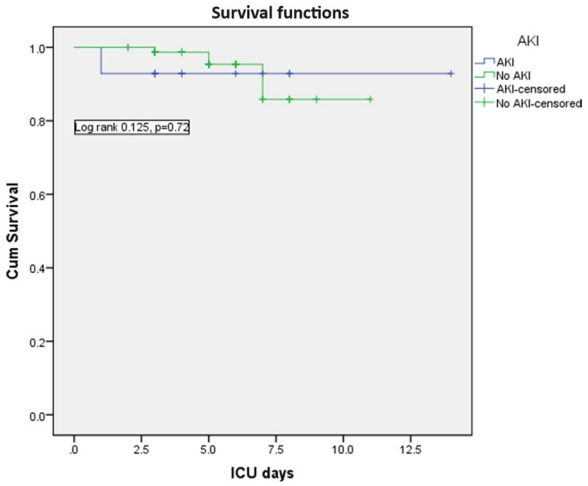
**Methods:** Prospective cohort of hospitalized patients from 2021 to 2023 in the HRAEV of Northeast Mexico. 91 post-cardiac surgery patients with extracorporeal circulation admitted to the ICU were included, authorized by the ethics committee. The objective was to evaluate the association of the use of dobutamine + levosimendan vs dobutamine with the presence of acute kidney injury during their stay, days of stay in the ICU and mortality. Continuous variables are described as means and standard deviation, categorical variables as frequencies and percentages. Relative risk was used and statistical significance was taken with a $p$ value < 0.05. A Kaplan–Meier survival curve was obtained.

**Results:** 91 patients were included and the observation was divided into two groups, dobutamine + levosimendan ($n = 25$) and dobutamine ($n = 66$), with a greater frequency of men in both groups, mean age (53 ± 16) and (57 ± 11), significant difference in the presence of hypertension as comorbidity 23% vs 42.2% ($p = 0.02$) and the presence of more patients in NYHA functional class II–III in the dobutamine group (Table 1). The incidence of AKI was 15.4% in total, and for the dobutamine + levosimendan group, it was 6.6% and for dobutamine 8.8% ($p = 0.16$), cardiovascular complications defined as arrhythmias 0% vs 8.7% ($p = 0.23$) and heart failure 2.1% vs 8.7% ($P = 0.13$). There was no difference in mortality during the ICU stay between both groups (Graph 1). Relative risk for acute kidney injury and use of dobutamine + levosimendan was 2.28 (95% CI 0.7–7.4, $p = 0.16$).

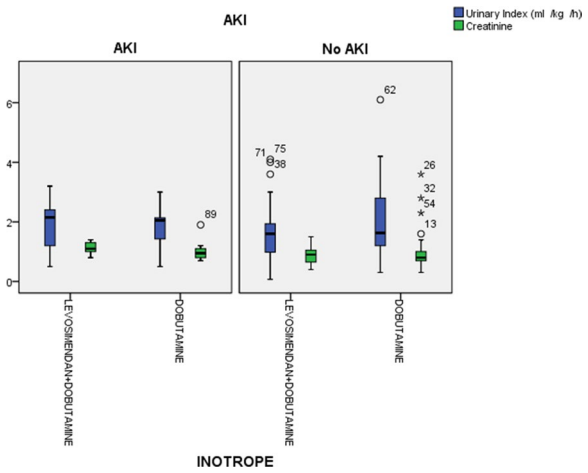
**Table 1**

| Demographics | Dobutamine + levosimendan | Dobutamine | *p* value |
|---|---|---|---|
| Gender (*n*/%) | M18 (19.8)/F7 (7.7) | M40 (44)/26 (28.6) | 0.31 |
| Age (years) | 53 (± 16) | 57 (± 11) | 0.28 |
| IMC (kg/m2) | 28.3 (± 4.3) | 30.2 (± 4.1) | 0.06 |
| Hypertension (*n*/%) | 21/23.3 | 38/42.2 | 0.02 |
| T2DM (*n*/%) | 15/16.5 | 36/39.6 | 0.64 |
| NYHA (I/II/III/IV) | 4.4/12.1/8.8/2.2 | 25.3/30.8/16.5/0 | 0.04 |
| EUROSCORE | 2.3 (± 1.5) | 2.1 (± 1.09) | 0.65 |
| LVEF (%) | 50 (± 14) | 55 (± 10) | 0.07 |
| pH | 7.35 (± 0.05) | 7.37 (± 0.05) | 0.30 |
| HCO3 (mEq) | 22.9 (± 3.4) | 22.7 (± 3.38) | 0.82 |
| ScvO2 (%) | 71 (± 7) | 72 (± 10) | 0.41 |
| Lactate (mmol/l) | 2.6 (± 2.1) | 2.4 (± 1.9) | 0.72 |
| Fluid balance (ml/1° day ICU) | 616 (± 817) | 449 (± 1786) | 0.65 |
| NT-proBNP | 1756 (± 2938) | 467 (± 668) | 0.001 |
| Creatinine (mg/dl) | 0.9 (± 0.2) | 1.5 (± 5.1) | 0.54 |
| MAP (mmHg) | 88 (± 16) | 91 (± 20) | 0.42 |
| ICU length of stay | 4.5 (± 2.6) | 4.6 (± 1.8) | 0.87 |
| Outcome (survival/death) | 25.3/2.2 | 70.3/2.2 | 0.3 |

**Conclusions:** In our study, we found no difference in the development of AKI in the intervention group vs dobutamine. Perioperative dobutamina + levosimendan is not associated with beneficial or harmful effects on days of stay in the ICU, mortality or acute kidney injury (Graph 2). There is a lack of large, high-quality randomized clinical trials that compare different therapeutic strategies with inotropes on postoperative outcomes. There is not much literature on the use of two inotropes in cardiac surgery.



**Graph 1 (abstract 001321)** Kaplan–Meier ICU days of AKI vs non-AKI



**Graph 2 (abstract 001321)** Box and whisker plots AKI and non-AKI vs dobutamine and dobutamine + levosimendan

### "Recovery roadmap after ICU"

S. Mariño Guerreiro[1], R. Garcia Del Moral[1], M. E. Poyatos Aguilera[1], J. Tejero Aranguren[1]
[1]Intensive Care Unit, Hospital Universitario Clínico San Cecilio, Granada, Spain
**Correspondence:** J. Tejero Aranguren
***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001323

**Introduction:** Improvements in critical care medicine have led to a marked increase in survivors of the intensive care unit (ICU). Surviving critical illness does not always equate to recovery, with its aftermath frequently complicated by post-intensive care syndrome (PICS) (1). The term PICS provides a framework for identifying the most common symptoms which fall into three domains: cognitive, physical, and mental health (2). There are numerous risk factors for the development of PICS including premorbid conditions and specific elements of ICU hospitalizations.
**Objectives:** To identify the incidence of PICS and evaluate the quality of life after ICU in the short and long terms.
**Methods:** This is a prospective observational study from 2019 to 2024. Setting: Medical ICU of a University Hospital with 18 beds and 1200 annual admissions.
Sample: Patients with ICU admission ≥ one week and at least one of the following: 3 ≥ days of mechanical ventilation, delirium or shock. Follow-up protocol: Assessment at 3, 6 and 12 months after discharge from ICU in a follow-up consultation. The scales were Barthel, SF-12, HADS, IES-6. A long-term follow-up assessment was also done between 3 and 4 years.
PICS was considered the presence of alterations in any of the three domains. Impairment in physical (P) domain was a deterioration in one category on the Barthel dependency scale with respect to admission to the ICU; impairment in cognitive domain (C) a score of > 3 points on the Pfeiffer test; and impairment in mental health domain (MH) a score of > 11 on the HADS test and/or 1.75 on the IES-6 score.
**Results:** A total of 88 patients were included in the follow-up. The overall incidence of PICS was 54.7% 3 months, 36.99% at 6 months and 8.22% at 12 months. The incidence of P-PICS decreases over time, from 24% at 3 months to 11% at 12 months. The other spheres do not follow this trend pattern, with a progressive increase in incidence in the MH-PICS, from 36.9% at 3 months to 46% at 12 months, and an upturn at 6 months in the C-PICS (22.6%). The mean follow-up was 4.38 years (dt 0.48). 12 patients (13.6%) died during the follow-up. At the last long term follow-up consultation, 49 patients were interviewed. The presence of PICS at 3 months was not related to survival (log rank test $p = 0.4$). 38 patients (43.1%) have had a hospital readmission during follow-up. Mean SF12 physical was 41.36 (dt 12.3) and 44.1 (dt 11.9). Scores were lower in the PICS group at 4 years for physical SF12 (52.91 vs 35.7, $p = 0.06$) but not for the mental health component (38.17 vs 40.87, $p = 0.87$).
**Conclusions:** The incidence of PICS varies over the follow-up time and the associated risk factors are different depending on the sphere studied. The health-related quality of life at long-term follow-up continues to be lower compared to the reference population. By identifying PICS and assessing the quality of life over time, this study contributes to a better understanding of the multifaceted impacts of critical care interventions on patient well-being.

***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001324

**Introduction:** Oxiris® (Baxter, Deerfield, IL, USA) is a hemodiafilter designed for renal replacement therapy, indicated to clear both cytokines and endotoxins [1,2]. In septic patients, its use has been demonstrated to be associated with lower 28-day mortality [3]. Considering the lack of specific recommendations on blood purification, physicians pragmatically prescribe Oxiris® based on their perception of patients' needs and treatment appropriateness.
**Objectives:** This study aims at clustering phenotypes of patients currently treated with Oxiris® and describing patients' short-term mortality, defined as death during the first 4 days of treatment, according to phenotypes identified with a principal component analysis [4,5].
**Methods:** This observational study is based on the OxirisNet Registry, an Italian, multicenter registry of critically ill patients undergoing treatment with Oxiris®. Patients were divided into two groups according to short-term mortality (4 days after treatment initiation with Oxiris®). Principal component analysis and clustering were used to identify clusters of patients who seem to benefit the most from Oxiris®.
**Results:** Among the 277 patients observed, 71 (25.6%) died within four days. As shown in Figure 1 and summarized in Table 2, the cluster analysis demonstrated that physicians mainly prescribed Oxiris® a) to support renal function postoperatively in patients with chronic kidney disease and systemic inflammation (Blue Cluster), b) to immunomodulate critically ill patients with systemic inflammation, in the absence of absolute or relative indications for renal support (Red Cluster), c) to support renal function and immunomodulate critically ill patients with abdominal septic shock (Green Cluster). The mortality rates associated with each cluster were 16.70%, 21.30% and 30.80% for the Blue, Red and Green Cluster, respectively.
**Conclusions:** Critically ill patients undergoing an extracorporeal blood treatment have a high mortality risk. Patients with no kidney dysfunction do not seem to benefit from treatment with Oxiris® in terms of mortality, regardless of their inflammatory clinical state. The identification of clusters of patients who benefit the most from Oxiris® membrane might be quintessential to guide clinical practice and design pragmatic trials to test its effectiveness.

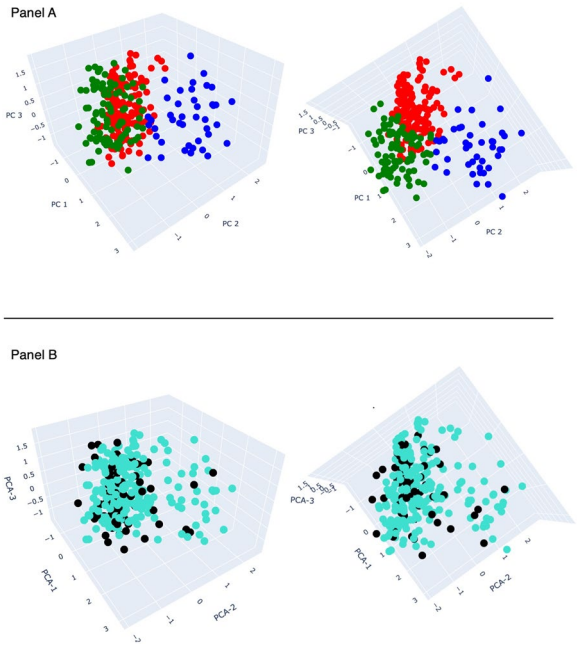

**Fig. (abstract 001324)** Panel A shows two projections of PCA analysis identifying the three clusters of patients treated with Oxiris®: Blue, Red and Green Clusters. In Panel B (using the same projections of Panel A), patients are distinguished according to short-term mortality (survivors in turquoise and non-survivors in black). Legends: PC-1 = Principal Component 1; PC-2 = Principal Component 2; PC-3 = Principal Component 3

**Introduction:** Chest radiography (CXR) is a routine imaging test in intensive care units (ICUs), owing to its ease and speed in detecting pleuropulmonary alterations as well as medical complications associated with the use of invasive devices, and also for monitoring the progression of the patient's disease and enabling the implementation of appropriate treatments. However, its routine use presents a series of controversies between daily or on-demand requests due to the rate of detection of complications, the potential risk of unnecessary or secondary treatments due to false positives, radiation exposure, associated costs, and possible complications derived from the procedure itself. Although the scientific literature on the benefits of restricting the routine use of chest radiography is limited, some studies suggest that it may be safe, and reduce costs and radiation exposure, without increasing the risk of complications, ICU length of stay, and mortality.
**Objectives:** To determine the percentage of routine CXRs with new findings and how many result in a change in clinical approach.
**Methods:** This is a retrospective study (September–October 2023) in patients admitted to the University Hospital of Guadalajara Intensive Care Unit.
**Results:** A total of 521 CXRs from 70 patients were evaluated. Most were men (65.71%), with a mean age of 59.48 ± 14.14 years. An average of 7.45 ± 9.6 CXRs per patient were performed, with an average length of stay of 7.1 ± 9.34 days. Of the total CXRs performed, 75.05% were routine and 24.95% were non-routine. Among the most frequent admission reasons were: respiratory 33.0%, digestive 15.7%, cardiological 15.4%, neurological 9.2%, and traumatic 7.7%, among others. 36.0% of CXRs showed findings: new device (central venous catheter, endotracheal device) 10.7%, pulmonary infiltrate 8.8%, device misplacement 8.1% (5.9% endotracheal tube), pleural effusion 6.3%, atelectasis 1.2%, and pneumothorax 1.0%. Findings were detected in 20.9% of routine CXRs and 81.6% of non-routine ones (Odds ratio: 3.41 CI 2.95–6.3, favours non-routine CXR). We found that out of the total CXR performed on patients in the ICU, 40.1% of them resulted in changes in clinical approach. Of these, 36.3% came from routine chest X-rays and 51.5% from non-routine chest X-rays (Odds ratio: 0.53 CI 0.35–0.80 against routine CXR). The most common changes in clinical approach were: modification of mechanical ventilation 20.7%, device repositioning 7.7%, and new device placement 5.4%.
**Conclusions:** Routine CXRs have limited utility compared to non-routine ones for obtaining new findings (24.95% vs. 75.05%).
The lower odds ratio associated with routine CXRs suggests the need for further exploration into their potential overuse while emphasizing the value of non-routine CXRs in guiding clinical management.
According to our results, the risk of not identifying changes by restricting the daily prescription of CXRs seems to be low.
Restricting the number of CXRs would likely result in economic savings and a reduction in radiation exposure.

***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001326

**Introduction:** Assessment of cognitive function is important for risk stratification and predicting the quality of life after transcatheter aortic valve replacement (TAVR) among the elderly. Although reduced preoperative neurocognitive function has been known to correlate with poor clinical operative outcomes after TAVR, limited study shows the change between preoperative and postoperative neurocognitive function.
**Objectives:** We wanted to determine the changes before and after TAVR according to domains of neurocognitive test battery.
**Methods:** From January 2021 to July 2022, 70 patient undergoing transcatheter aortic valve replacement under monitored anesthesia care were included. The patients had Seoul Neuropsychological Screening Battery (SNSB) which is one of the standardized neurocognitive test batteries widely used in Korea. We tested specific domain of attention, language function, visuospatial function, memory, and executive function a day before TAVR and 3-month follow-up after hospital discharge. Total of 60 patients completed the 3-month follow-up at outpatient clinic. Z-scores were based on normative means and standard deviations (SD), combined into a composite z-score. Scores of standard deviation (-) 1.5 or below the normative were defined as abnormal function.
**Results:** The prevalence of mild cognitive impairment measured by SNSB reduced from 48.6% before TAVR to 26.7% after TAVR. The median composite z-score increased significantly 3-month after TAVR compared to before TAVR (−0.73 SD [−1.58, −0.31] to −0.61 SD [−1.31, 0.1] below the normative mean, $P=0.003$). In specific, language-related function ($P=0.004$), memory function ($P=0.001$), psychomotor speed of executive function ($P=0.006$) showed significant improvement after TAVR (Table 2). Of 34 patients who showed preoperative mild cognitive impairment 38.2% patients showed improvement to normal cognitive function after TAVR. The proportion of patients who improved to normal cognitive function in each domain was as follows: attention (75.0%), language (50.0%), visuospatial function (14.3%), memory function (71.4%), and executive function (46.7%) (Figure 1).
**Conclusions:** Patients undergoing TAVR showed significant portion of mild cognitive impairment before TAVR. However, cognitive function significantly improved 3-month after TAVR and reduced the number of patients with mild cognitive impairment. Further studies are needed to find the mechanism of improvement in cognitive function after TAVR.

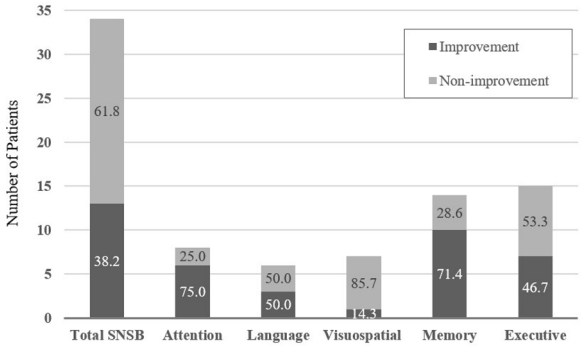

**Table 1 (abstract 001326)** Baseline characteristics of patients who were previously normal cognitive function and who had mild cognitive impairment

| | Normal (n = 36) | With MCI (n = 34) | *P* |
|---|---|---|---|
| **Baseline characteristic** | | | |
| Age (years) | 81 (78, 83) | 83 (81, 86) | 0.03 |
| Male sex | 20 (55.6) | 12 (35.3) | 0.1 |

**Introduction:** The current therapies' innovations have led to improvement in prognosis and life expectancy of solid cancer patients and, therefore, higher eligibility to Intensive Care Unit (ICU) admission, mainly due to acute medical pathology.
**Objectives:** This study aim was to evaluate factors that influence ICU, one-year and two-year mortality of solid cancer patients admitted for acute medical pathology.
**Methods:** A retrospective study was conducted, including patients with solid malignancies admitted for medical reasons in the ICU from January/2017 to January/2022. Patients submitted to surgery in the 30 days prior admission were excluded. ICU, one-year and two-year after discharge mortality were accessed and correlated with clinical factors and severity scores obtained in the first 24 h.
**Results:** A total of 229 patients were admitted in the ICU, with a median age of 65 years (IQR 17), predominantly male ($n=151$, 65.9%), with ECOG Scale 0/1 ($n=124$, 54.1%). The most frequent primary tumor sites were gastro-intestinal ($n=60$, 26.2%), head and neck ($n=44$, 19.2%) and lung ($n=41$, 17.9%), predominantly stage IV ($n=82$, 35.8%) and with no malignancy recurrence/progression ($n=183$, 79.9%). 72.5% ($n=166$) presented with sepsis and, of these, 45.2% ($n=75$) with multiorgan dysfunction. The median length of stay was 3 days (IQR 6), 52.4% ($n=120$) required invasive mechanical ventilation (IMV) with a median IMV time of 79 h (IQR 139.5). The overall mortality in the ICU was 25.3% ($n=58$), among survivors, one-year mortality was 45.0% ($n=77$) and two-year mortality was 22.3% ($n=21$). Age, sepsis with multiorgan dysfunction, IMV and the SAPS II value were predictors of mortality. The presence of chronic lung disease, multiple comorbidities, worst admission performance status and advanced cancer staging were predictors of one-year mortality. Type of malignancy, previous treatments and recurrence/progression of malignancy did not influence mortality.
**Conclusions:** The multiplicity of available treatments, as well as the emerging of precision medicine programs with targeted therapies, are transforming cancer into a chronic day-to-day disease, that influences short and long ICU outcomes globally as others comorbidities. The results suggest that ICU mortality did not correlate with type, stage nor recurrence/progression of malignancy, as it is related to the severity of the acute illness at admission. The one-year mortality appears to be correlated to worst performance status, presence of multiple comorbidities and advanced refractory malignancy, as expected in the literature. The two-year mortality has no clear correlating factors, which reinforces the chronic disease overview.

### Analysis of mortality in severely burned patients admitted to an Intensive Care Unit

B. Tineo Martínez[1], F. J. Reina-Martínez[1], A. Delgado Barroso[1], Á. Lopez De Tejada[1], D. Cuenca Apolo[1]
[1]Critical Care Unit, Virgen del Rocío University Hospital, Sevilla, Spain
**Correspondence:** B. Tineo Martínez
*Intensive Care Medicine Experimental* 2024, **12(suppl 1):**001329

**Introduction:** The care of severely burned patients in the intensive care setting presents considerable challenges, with a mortality rate reflecting the complexity of their management. Analyzing the various determinants of severe complications in this patient population poses a challenge, as does understanding their impact on mortality. By comprehending these factors, we can better guide our strategies to improve outcomes in this highly vulnerable population.
**Objectives:** Analyzing the epidemiological and clinical characteristics, as well as the development of complications in severely burned patients admitted to an Intensive Care Unit, identifying factors that may influence increased mortality in these patients.
**Methods:** This is a descriptive, retrospective, and observational study of patients with severe burns admitted to a third-level hospital ICU over a period of three years. Background information (Charlson comorbidity index) and clinical variables were collected, including the burned body surface area, fluid resuscitation in the first 24 and 48 h (Parkland formula), severity scores such as SOFA and ABSI, days on mechanical ventilation, presence of ventilator-associated pneumonia, as well as length of stay in the ICU and hospital. The study aimed to identify patients who died and the cause of death (associated with hypoxemia or sepsis).
**Results:** The study included 85 patients, of whom 23 died (27.1%). The mean age was $57.9 \pm 13$ in the deceased group and $41.59 \pm 14.9$ in the survivors ($p < 0.001$). In the deceased group, the mean Charlson comorbidity index was $1.5 \pm 1.4$ vs $0.67 \pm 1.38$ in survivors ($p$ 0.023). Severity scores showed higher values in the deceased group: SOFA of $8.26 \pm 2.5$ vs $4.23 \pm 2.2$ in survivors ($p$ 0.01), ABSI of $10.6 \pm 1.92$ vs $7.62 \pm 2.51$ in survivors ($p$ 0.001), as well as statistical significance ($p$ 0.001) when analyzing the burned body surface area (deceased $50.5 \pm 18.33$ vs survivors $32.86 \pm 19.35$). Similarly, more aggressive fluid resuscitation (adjusted by the Parkland formula) in the first 24 h was associated with higher mortality (deceased 16,400 ml $\pm$ 6,600 vs survivors 10,700 $\pm$ 5,900, $p$ 0.002), with no significant difference between both groups in resuscitation in the first 48 h. The most common burn mechanism in both groups was deflagration (60% of cases). Septic shock predominated as the cause of death (n 15, 68.1%). There was no statistical significance ($p < 0.05$) regarding the analysis of days on mechanical ventilation or ventilator-associated pneumonia in this study concerning mortality.
**Conclusions:** In our experience, medical history, burned body surface area, severity scores at admission, and initial fluid resuscitation play important roles in the outcome of severely burned patients. Severe burns remain a significant cause of mortality in the ICU, either due to the consequences of the thermal trauma itself or potential serious complications during their hospital stay.

### Neurological Pupil Index (NPi) for early prediction of clinical neurological deterioration

M. Polato[1], C. Dehout[2], A. Van Engelgem[1], M. Petrosino[3], S. Galimberti[4], M. Oddo[5], F. S. Taccone[1], G Citerio[3]
[1]Soins Intensif, ULB Erasme, Anderlecht, Belgium; [2]Soins Intensif, ULB Erasme, Brussels, Belgium; [3]School of medicine and surgery, University of Milano-Bicocca, Monza, Italy; [4]School of Medicine and Surgery, University of Milano-Bicocca, Milano, Italy; [5]Department of Intensive Care Medicine, Lausanne University Hospital, Lausanne, Switzerland
**Correspondence:** M. Polato
*Intensive Care Medicine Experimental* 2024, **12(suppl 1):**001330

**Introduction:** The recently published ORANGE study1 described the association of the Neurologic Pupil Index (NPi), measured via an automated pupillometry, with neurologic outcome and mortality after acute brain injury (ABI). No data on the predictive value of NPi for clinical neuroworsening are available.
**Objectives:** To assess the relationship between changes in NPi values and the occurrence of clinical neuroworsening in patients with head trauma.
**Methods:** Secondary analysis of traumatic brain injury (TBI) patients included in a previous multicenter, prospective, observational cohort study. NPi measurements and clinical evaluation were performed at least six times per day from recruitment day up to seven days maximum. The lowest NPi value between both eyes was used. Clinical neuroworsening was defined as one point decrease in the motor Glasgow Coma Scale (mGCS). In all patients, NPi data in the days with neuroworsening (starting from the previous day) were compared to those without neuroworsening (using the same timeframe). A multilevel mixed-effects logistic regression model with a random intercept was employed to estimate the association between the NPi and clinical neuroworsening.
**Results:** Among the 514 patients in the study, 224 (44%) suffered from TBI and were included in the final analysis. Median age was 54 (34–72) years, and 170 (76%) patients were male; 66% of patients had GCS on admission < 9, while 44% had a mGCS of 5–6. Over a total of 2950 days on available monitoring, 263 (8.9%) episodes of clinical neuroworsening were identified. In the multilevel mixed-effects logistic regression model, a reduction of NPi was associated with a decreased probability of clinical neuroworsening (odds ratio 0.93 [0.86–1.00]; $p = 0.054$).
**Conclusions:** According to this analysis, we observed an association between changes in NPi values and the occurrence of clinical neuroworsening.

**Correspondence:** N. Patel
*Intensive Care Medicine Experimental* 2024, **12(suppl 1):**001331

**Introduction:** General anaesthesia reduces functional residual capacity (FRC), which is mainly contributed by formation of atelectasis in the dependent lung region. Atelectasis causes postoperative hypoxemia and may contribute to the development of postoperative pulmonary complication (POPC), which is common in open abdominal surgeries. In comparison to patients with pressure support ventilation, risk of atelectasis is higher in patients with manual support due to pain induced respiratory muscle restriction, fatigue, inadequately restored FRC. PSV applies a fixed amount of pressure through each breath and thus augments one's respiration and helps in preventing post op atelectasis.
**Objectives:** The primary objective was to compare the effects of pressure support ventilation and spontaneous ventilation (control) during emergence and extubation on incidence of atelectasis and oxygenation during extubation and in post-anaesthesia care unit (PACU) in patients undergoing major open abdominal surgeries.

- Comparison of PaO2 between both groups.
- Events of Spo2 < 92% during PACU stay and 48 h after surgery in both groups.
- Comparison of POPC.
- Duration of hospital stay.
- Extubation time (Time taken from start of extubation protocol till extubation).

**Methods:** It is a single centred randomized controlled double-blinded trial. The sample size was calculated to be 134. We have done interim analysis after recruitment of 62 patients ($n = 62$). Patients were randomly assigned to pressure support ventilation group ($n = 27$) and control group ($n = 32$). During emergence, PSV was used in the pressure support group versus intermittent manual assistance in the control group. Lung ultrasound score was noted at four time points (T1-T4). POPC (post-operative pulmonary complication) was assessed till third postoperative day by Melbourne Group Scale. All patients were followed till hospital discharge and duration of postoperative hospital stay was also noted.
**Results:** Incidence of atelectasis was lower in PSV group than control group during both extubation and in PACU extubation—2 of 27 [7%] vs. 10 of 32 [28%] $P = 0.052$; at 30 min in PACU—4 of 27 [14%] vs 12 of 32 [34%] $P = 0.14$). PaO2—pressure support group than in control group in PACU (131?70 mmHg vs 115?57 mmHg $P = 0.4$). There was no difference in incidence of Spo2 < 92% during 48 h postoperatively between the groups ($P = 0.25$). There were no difference in incidence of POPC ($P = 0.2$) or duration of extubation ($P = 0.2$) or duration of hospital stay ($P = 0.26$) between two groups.
**Conclusions:** The incidence of postop lung atelectasis was lower and PaO2 was higher in patients who received pressure support ventilation compared to control group.

**Topic:** Acute respiratory failure and mechanical ventilation

**Introduction:** The ratio of SaO2/FiO2 has been recently proposed as a surrogate of PaO2/FiO2 in the finding of ARDS severity. In this study, we investigated the relationship between these two variables in theory and practice.
**Methods:***Effect of pH: Theory:*
1. We compute, at a given SpO2/FiO2 ranging from 50 to 350, what was the FiO2 fraction which generated 97% hemoglobin oxygen saturation;
2. We then iteratively computed the PaO2 corresponding to that FiO2 fraction (Kelman's equation) in the standard hemoglobin oxygen dissociation curve (pH 7.4, PaCO2 40 mmHg, temperature 37 °C);
3. The same procedure was repeated using the hemoglobin oxygen dissociation curve at pH of 7.0 and 7.8, according to Kelman.

SpO2/FiO2 and PaO2/FiO2 relationship in practice
In 304 ARDS patients, we compared the SpO2/FiO2 and PaO2/FiO2 measured at 5 and 15 cmH2O of PEEP.
**Results:** In Panel A and Panel B, we show the effect of pH on the relationship between PaO2/FiO2 and SpO2/FiO2. As an example, at FiO2 of 0.4, patients classified as moderate according to PaO2/FiO2 classification (Panel B), may shift to the mild category if pH is 7.0 and to the severe category if pH is 7.8 (Panel A). Note that the blood pH is only one of the several variables that may affect the oxygen dissociation curve (as PCO2, 2,3-DPG, and temperature). The relationship between PaO2/FiO2 and SpO2/FiO2 in real life is presented in Panel C; as shown, a PaO2/FiO2 of 100 may be associated, as an example, with a SpO2/FiO2 ranging from 100 to over 300.

**Conclusions:** The use of SpO2/FiO2 as a surrogate of PaO2/FiO2 is highly questionable and may lead to inadequate clinical decisions when used to classify the ARDS severity instead of the PaO2/FiO2.

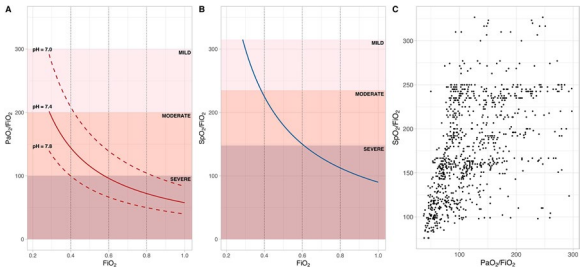

**Fig. (abstract 001332)** Comparison between PaO2/FiO2 and SpO2/FiO2. Panel A represents a theoretical model referred to PaO2/FiO2 at different FiO2 computed with Kelman's equation at three different pH. Panel B represents a theoretical model referring to SpO2/FiO2 at different FiO2; this second model is computed starting from SpO2/FiO2, ranging from 50 to 350, and SpO2 of 97% (see text for mathematical details). Panel C represents the relationship between PaO2/FiO2 and SpO2/FiO2 in a population of 304 ARDS patients

**Introduction:** Maintaining fluid homeostasis is an integral part of caring for critically ill patients.
When a critically ill patient has excess fluid in their body, it is associated with organ failure, higher morbidity and mortality. There are multiple shortcomings to the conventional techniques for monitoring changes in fluid status. Subcutaneous edema formation may result from positive cumulative fluid balance, which can be measured objectively with ultrasonography (USG).
**Objectives:** In our study, we used USG to quantify subcutaneous edema on days 1, 3, and 7 of the ICU stay, assessed its prognostic utility in predicting 28-day mortality, and analyzed how it correlated with cumulative fluid balance (CFB).
**Methods:** This study is being conducted in AIIMS Delhi from November 2023 to December 2025. Patients admitted in ICU within 72 h of hospitalization after meeting the inclusion criteria are being enrolled. Ultrasonography is performed at 12 defined regions, and ultrasonographic subcutaneous edema is scored between 0 and 4 as per the FLUID protocol (*). The total USG scores at day-1, 3, 7, along with the change in the USG scores at day3 (day3-day1), day7 (day7-day1) are calculated.
We are reporting an interim analysis of the patients enrolled till 10 March 2024.
Data have been analysed using SPSS software version 29.0.
**Results:** 44 patients (18 surgical, 26 medical) were included in this interim analysis. The median age was 33.5 years (IQR: 25–44). 15

patients had ICU stay < 7 days (7 died, 8 shifted out) and 28-day mortality was 42%. The median CFB on day-1, 3 and 7 were + 1050 ml (range: − 800 ml to + 4750 ml), + 1600 ml (− 1350 ml to + 3750 ml), and + 2500 ml (+ 80 ml to + 4595 ml), respectively.
The total USG score and CFB at day-1 did not correlate with the 28-day mortality. The change in USG score at day-3 and 7 weakly correlated with CFB at day-3 ($r = 0.25$, $p = 0.03$) and CFB at day-7 ($r = 0.37$, $p = 0.038$), respectively. The 28-day mortality showed moderate and strong correlation with the change in USG score at day-3 ($r = 0.52$, $p = 0.005$), and the change in USG score at day-7 ($r = 0.78$, $p = 0.001$), respectively, whereas it showed weak and moderate correlation with CFB at day-3 ($r = 0.32$, $p = 0.03$) and CFB at day 7 ($r = 0.58$, $p = 0.001$), respectively.
A decreasing trend in the USG score by day 7 from day 1 or day 3 showed very high correlation with 28-day ICU mortality ($r = 0.82$, $p = 0.0001$). Receiver operator curve which was plotted for the same showed an area under the curve of 0.90 (CI: 0.88-0.92, $p = 0.0001$). Cutoff value of -8 showed sensitivity of 100% and specificity of 82%, respectively.
**Conclusions:** The ultrasonographic subcutaneous edema score performed better in predicting the 28-day mortality in ICU patients and had a limited correlation with cumulative fluid balance. One novel and more precise method for determining the cumulative fluid status of ICU patients is subcutaneous ultrasonography.

**Introduction:** Pre-existing renal dysfunction before liver transplantation (LT) is related to the transition to post-LT renal complications, which increases in-hospital stay, graft failure, and mortality. Although living donor liver transplantation (LDLT) is known to have superior post-transplant outcomes compared with deceased donor liver transplantation (DDLT), a previous study among patients with low eGFR showed worse survival for eGFR-low patients receiving LDLT compared to DDLT.
**Objectives:** We attempted to compare medically matched transplant recipients and evaluate the effect of pre-existing renal dysfunction on short-term graft survival of LDLT versus DDLT.
**Methods:** This was a retrospective cohort study of 1,530 LDLT recipients and 549 DDLT recipients between May 1995 and December 2021. To reduce selection bias, a 1:1 ratio propensity score-matched analysis between LDLT recipient and DDLT recipient was performed. After matching, 445 cases in each group were additionally divided into subgroups based on the presence of pre-LT renal dysfunction. Pre-LT renal dysfunction was defined as serum creatinine level ≥ 1.5 mg/dL at the time of LT or the need for renal replacement therapy within 3 months before LT. Six-month graft failure, and mortality between groups were analyzed.
**Results:** Of the 445 patients in each group, the prevalence of pre-LT renal dysfunction was 162 (36%) in LDLT group and 178 (40%) in DDLT group. The incidence of 6-month graft failure was significantly higher in patients with pre-LT renal dysfunction regardless of donor type ($p = 0.002$ in LDLT and $p = 0.016$ in DDLT) (Table 2). However, no statistically significant difference was found in 6-month graft failure and 6-month mortality between DDLT recipients (D group) and LDLT recipients with pre-LT dysfunction (LR group) ($p = 0.435$ and $p = 0.31$, respectively). After adjustment, the Cox proportional hazard regression analysis revealed that the donor type of LT and the presence of pre-LT renal dysfunction were independent predictors of 6-month graft failure [Hazard ratio (HR) 1.73 (95% CI, 1.11–2.61) and HR 1.66 (95% CI, 1.03–2.69), respectively]. In addition, compared to group LR, there was no significant difference in graft failure risk between the D and DR groups (Figure 1).
**Conclusions:** In conclusion, the presence of pre-LT renal dysfunction at the time of LT shows negative effect in both LDLT and DDLT. Interestingly, LDLT recipients with pre-LT renal dysfunction did not show superior graft and patient survival over DDLT recipients without pre-LT renal dysfunction. Our findings suggest that optimal renal function is an important factor for postoperative liver transplantation outcome regCardless of the donor type.

### Greek health care workers' compliance concerning the hand hygiene in the Intensive Care Unit

A. Tsoukala[1], V. Karamouzos[2], T. Barberis[2], D. Bousis[2], K. Zafeiri[2], D. Aretha[2], F. Fligou[2]

***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001335

**Introduction:** Intensive Care Units (ICUs) are among the hospital wards with the highest prevalence of healthcare acquired infections (HAIs) leading to increased length of stay, significantly higher costs, morbidity, and mortality. Most HAIs can be avoided with the implementation of infection prevention measures among which hand hygiene is of paramount importance in the reduction of infection transmission in hospitals [1].
**Objectives:** To measure hand hygiene compliance of health care workers before and after implementing an educational program according to WHO guidelines in a Greek University hospital.
**Methods:** The study was conducted in the ICU of Patras University Hospital and was divided into three parts, assessment of baseline compliance, training, and finally compliance assessment after training. Total duration was three months and the method used for measuring compliance was "direct observation".
**Results:** The overall hand hygiene compliance rate increased from 33.3% to 49.4%. Hand washing was the preferred hand hygiene technique and its rate increased from 27.8% to 33.4% followed by alcohol-based hand rubbing reaching 16% from 5.5%. The use of gloves as a substitution for hand hygiene was reduced from 66.8% to 49.6%. Among healthcare workers (HCW), nurses almost doubled their compliance rate (37.5% to 60.6%), whereas doctors rates remained unchanged by the training program (29.6% to 29.8%). Hygiene moment rates that were affected the most were before touching a patient (10% to 21%), after touching a patient (59.9% to 73%) and after touching patient surroundings (46.2% to 56.7%). Nurses increased their compliance rates in all five hygiene moments, doctors in the first and the fifth moment and the rest of the personnel in the first and fourth moment. Alcohol-based handrub use increased among nurses from 23.2% to 76.8%, among doctors from 33.3% to 66.7% and remained at 50% for the rest HCW. Finally, hand washing with soap rate was increased among nurses from 40.7% to 59.7% and decreased among doctors and the rest HCW from 55.9% to 44.1% and from 54.5% to 45.5%, respectively.
**Conclusions:** The results of this study demonstrate that a training program can be effective and successful in increasing overall hand hygiene compliance among most healthcare workers. Further research is needed to elucidate the causes that contributed to the physician's low compliance rates and lack of improvement after training. Education and training of health care workers in hand hygiene are recommended as essential practices for improving hand hygiene but differences between HCW groups suggest the need for a tailored training program.

### Effects of ventilator settings on the indexes of inferior vena cava in critically ill patients during respiratory support with spontaneous activity

V. Parat[1], K. Trongtrakul[1]
[1]Internal Medicine, Faculty of Medicine, Chiang Mai University, Chiang Mai, Thailand
**Correspondence:** K. Trongtrakul
***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001337

**Introduction:** The distension of the inferior vena cava (IVC) has been widely accepted for assessing fluid responsiveness in critically ill patients undergoing passive positive pressure ventilation. However, the use of ultrasound to assess the IVC poses challenges, particularly regarding whether the IVC collapses or distends in critically ill patients receiving ventilatory support with spontaneous activity.
**Objectives:** Therefore, this study aimed to investigate the impact of pressure support ventilation (PSV) on the likelihood of IVC collapse or distension.
**Methods:** A total of 12 PSV-mode ventilator settings, comprised of pressure support (PS) and positive end-expiratory pressure (PEEP) at 0/0, 0/5, 0/10, 5/0, 5/5, 5/10, 10/0, 10/5, 10/10, 15/0, 15/5, and 15/10 cmH2O, were randomly assigned to patients to minimize biases from period and sequence effects. After two minutes on each ventilator setting, we observed whether the IVC collapsed or distended during the inspiratory phase of ventilation and measured IVC diameter at end inspiration (IVCei) and end expiration (IVCee). The IVC collapsibility index (cIVC) and IVC distensibility index (dIVC) were calculated as (IVCee-IVCei)/IVCee*100 and (ICVei-ICVei)/IVCee*100, respectively.
**Results:** Sixty adult ICU patients were involved, with an average age of 67 and 55% male. The IVC were mostly collapse at almost 85% of all observations. The probability of IVC collapse was notably higher at lower PS and PEEP levels, while the IVC exhibited a trend toward distension at higher ventilator settings. The IVC collapsed at low levels of PS/PEEP (at 0/0 and 0/5, probability of IVC collapse = 100%). The probability of IVC collapse was lower at higher PS/PEEP (at 10/10 and 15/10, probability of IVC collapse = 82% and 60%, respectively). Furthermore, there were greater calculated cIVC values at lower levels of PS/PEEP compared with higher levels. For instance, the cIVC at PS/PEEP 0/0, 0/5, 10/10, and 15/10 cmH2O were 38%, 30%, 20%, and 19%, respectively. A greater level of PS had a significantly negative impact on the cIVC, with $p < 0.001$ at all PEEP levels (Fig. 1A). This negative impact was also found when the level of PEEP was increased, with $p < 0.001$ at all PS levels (Fig. 1B).
**Conclusions:** In patients ventilated with spontaneous activity, it was observed that the IVC often exhibited collapsibility, especially at low levels of PS/PEEP. In addition, the cIVC was found to be lower with high levels of PS and PEEP. This might be one reason that limits the interpretation of IVC to assess FR among patients with spontaneous activity.

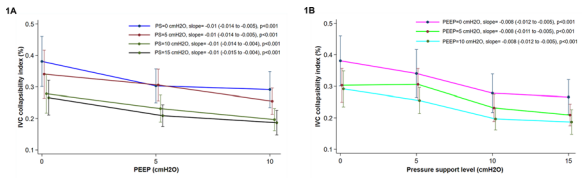

**Fig. (abstract 001337)** The IVC collapsibility index according to the levels of pressure support (1A) and positive end expiratory pressure (1B)

### Respiratory failure in severe burn patients: prevalence and risk factors

F. J. Reina-Martínez[1], B. Tineo Martínez[1], A. Delgado Barroso[2], Á. Lopez De Tejada[1], D. Cuenca Apolo[2]
[1]Intensive Care, Virgen del Rocío University Hospital, Sevilla, Spain; [2]Critical Care Unit, Virgen del Rocío University Hospital, Sevilla, Spain

***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001340

**Introduction:** Severe burn injury constitutes a complex pathology that involves longer ICU and hospital stay compared to other critical care entities, with a high mortality rate in published European registries and studies. Up to 34% of death causes after the first 48 h is due to acute respiratory failure, yet its prevalence among burn patients, severity and etiology are not well documented.
**Objectives:** To determine the prevalence of hypoxemic respiratory failure in severe burn trauma patients and the risk factors associated with its occurrence.
**Methods:** Analytical, observational, and retrospective study of patients admitted to a third-level ICU for severe burn injury between 2021 and 2023. Demographic variables, comorbidities using the Charlson index, burn-related factors (mechanism, burned body surface area (BSA), fluid therapy administered in the first 24 and 48 h, airway involvement, and inhalation syndrome), onset of severe hypoxemia (PaO2/FiO2 < 200) in the first 14 days and its etiology (adult respiratory distress syndrome (ARDS), fluid overload, respiratory infection (VAP)), hospital mortality, and ICU and hospital stay are collected. Means and standard deviations of quantitative variables, as well as proportion of qualitative variables are calculated. Student's *T*-test and Chi-square test are used for hypothesis testing. For the statistical analysis, SPSS package (v. 25) is used.
**Results:** A total of 70 patients were registered, with a mean age of 45 years (SD 16). The observed population was constituted mostly by males (54%) with a low Charlson comorbidity index (1, SD 1) and mean BSA of 39% (SD 21).
Thirty-five patients (50%) presented hypoxemic respiratory failure in the first 14 days, with a clinical onset on the 6th day as mean (SD 11). 80% had clinically documented fluid overload (OR 132, 95% CI [15, 238]) and 82.4% had a VAP diagnosis when respiratory deterioration occurred (OR 12.9, 95% CI [4, 41]). 57% met ARDS criteria.
An association was observed between the onset of hypoxemia and higher BSA (34% vs. 45%, $p = 0.03$); and higher score on the Abbreviated Burn Severity Index (ABSI) (8 vs. 9, $p = 0.019$). Fluid therapy administered in the first 24 h was also associated with this (10,338 vs. 14,740 ml, $p < 0.01$). Airway involvement or inhalation were not associated with a higher risk of hypoxemia.
Regarding the course of the disease, 68% of patients required neuromuscular blockade, and 11 subjects (31.4%) prone positioning, with an average improvement in PaO2/FiO2 of 108 (SD 69). 40.6% required tracheostomy, and associated with longer ICU stay (33 vs. 14, $p = 0.05$) and days of mechanical ventilation (23 vs. 7, $p < 0.01$). Mortality was higher but not significant compared to patients who did not experience hypoxemia (37% vs. 17%, OR 2.8 [0.93, 8.78]).
**Conclusions:** In our center, the incidence of moderate-severe hypoxemic respiratory failure in the first 14 days is high (50%). Factors associated with its development are VAP, fluid overload, high ABSI score, and greater fluid therapy in the first 24 h. Its onset determines higher mortality and longer ICU stay.

***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001345

**Introduction:** The increasing incidence of cancer and technological advancements highlight the growing importance of oncology in the ICU, complicating decisions regarding intensive treatment. Collaboration between oncologists and intensivists is crucial for establishing admission guidelines. Admission to the ICU may not involve new treatments but intensive monitoring to optimize existing measures and align treatment with the patient's values and goals.

**The decision not to admit to the ICU requires a comprehensive evaluation of the patient, considering their cognitive, functional, and clinical status, preferences, comorbidities, and prognosis. To identify the variable or combination thereof that best predicts the probability of ICU admission is key.**
**Methods:** This is a prospective observational study that includes patients over 18 years old with solid-organ tumors experiencing an acute event and requiring evaluation by the intensive care team for ICU admission.
**Results:** The total cohort consists of 215 patients, of which 173 were admitted to the ICU. We found a higher probability of admission in men than in women (OR = 2.62, [95% CI = 1.10–6.23]) ($p = 0.029$) and a lower probability of admission if the patient was a smoker (OR 0.27, [95% CI = 0.09–0.80]) ($p = 0.018$).
Significant differences were found between admitted and non-admitted patients in the presence of heart disease and renal insufficiency. 28.57% ($n = 12$) of patients with heart disease were not admitted to the ICU, while only 14.45% ($n = 25$) of patients were admitted ($p = 0.038$). Regarding renal insufficiency, 11.90% ($n = 5$) of non-admitted and 2.31% ($n = 4$) of admitted patients had this condition ($p = 0.005$).
Regarding tumor status, patients in stage II and stage III had a reduced risk of ICU admission by 97–98% compared to patients in stage I (OR = 0.03 [95% CI = 0.01–0.16] for stage II) and (OR 0.02 [95% CI = 0.00–0.13] for stage III). Patients in progression status were 86% less likely to be admitted to the ICU than those in induction status (OR = 0.14, (OR = 5.94, [95% CI = 0.05–0.39]).
34.68% ($n = 60$) of patients who had undergone surgical treatment were admitted to the ICU, however, only 11.90% ($n = 5$) of those with

such treatment were not admitted to the ICU. All patients in neoadjuvant treatment were admitted to the ICU and no patient in palliative treatment did so. Patients undergoing previous surgical treatment increased the risk of ICU admission by 6 times compared to those who had no oncological treatment (OR = 5.94, [95% CI = 1.59–22.15].
Patients with ECOG 2 or Karnofsky 70–50 have a significantly lower probability (OR = 0.05 [95% CI = 0.01–0.14]) ($p < 0.001$) of being admitted to the ICU compared to those with ECOG 0–1 or Karnofsky 100–80, respectively. Patients in ECOG 3–4 or Karnofsky 40–10 situations have an even lower probability of admission to the ICU (OR = 0.02 [95% CI = 0.00–0.09]) ($p < 0.001$).
The models evaluated in this study comprise different combinations of relevant clinical variables. Model 1, includes the weighted sum of the following variables: ECOG, tumor status, vital prognosis, oncological disease status, age, former smoker status, tumor extent, and renal insufficiency. Subsequent models (2, 3 and 4) represent variations of Model 1, each selectively removing one or more specific variables. In Model 2, the ECOG was excluded; in Model 3, ECOG and tumor status; in Model 4, ECOG, tumor status and vital prognosis.
Graph 1 shows the predictive capability of these models for ICU admission. The results revealed that Model 1 had the highest AUC of 0.962 (95% CI: 0.939–0.985), followed by Model 2 with an AUC of 0.952 (95% CI: 0.926–0.979).
**Conclusions:** In our work, we present different predictive models for income in patients with solid-organ tumors experiencing an acute event. The model that encompasses the ECOG scale, tumor status, vital prognosis, oncological disease status, age, former smoker status, tumor extent, and renal insufficiency is the one that best predicts the probability of admission to the ICU.

## The mechanism of ACE2/MasR/ERK signaling pathway involved in LPS-induced inflammatory injury of human pulmonary microvascular endothelial cells

J. Wang[1], H. Wang[1], H. Zhao[1], Y. An[1]
[1]Department of Critical Care Medicine, Peking University People's Hospital, Beijing, China
**Correspondence:** J. Wang
***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001349

**Introduction:** The main pathophysiological features of acute lung injury and acute respiratory distress syndrome (ALI/ARDS) are damage of pulmonary microvascular barrier, and overactivation of the inflammatory cascade. Angiotensin converting enzymes 2 (ACE2) may reduce the inflammatory response by enhancing angiotensin-(1-7) [Ang-(1-7)] and its receptor (Mitochondrial assembly receptor, MasR).
In this study, the inflammatory injury model of human pulmonary microvascular endothelial cells (HPMECs) induced by lipopolysaccharide (LPS) was used to investigate the dose-related changes in ACE2 expression. We also used the ACE2-specific agonist DIZE and antagonist MLN-4760 to preliminarily elucidate the mechanism of ACE2 regulation of the pulmonary microvascular barrier in ARDS. Trying to find theoretical basis for the identification of potential therapeutic targets for ARDS.
**Methods:** 1. Establishment of an LPS-induced acute lung injury cell model.
2. The effect of activating or inhibiting ACE2 on cell damage and related protein expression in HPMECs. HPMECs were pre-cultured with $2 \times 10\text{-}5$ M ACE2 agonist DIZE for 12 h, then 100 ng/ml LPS was added for 24 h; HPMECs were pre-cultured with 10-4M ACE2 antagonist MLN-4760 for 30 min then 100 ng/ml LPS was added for 24 h.
3. The effect of inhibiting MasR on cell damage and related protein expression in HPMECs. HPMECs were pre-cultured with $5 \times 10\text{-}5$ M MasR antagonist A779 for 4 h, then 100 ng/ml LPS was added for 24 h.
**Results:** 1. Dose experiments showed that: LPS stimulation caused a decrease in the cell viability of HPMECs and an increase in LDH activity released into the culture medium compared to the control group. In addition, the cell viability became worse with increasing concentrations of LPS stimulation in a dose-related manner;
2. LPS stimulation promoted ACE2 protein expression. Compared with the control group, ACE2 protein levels were increased in HPMECs at different doses of LPS for 24 h with the most significant increase in ACE2 in the 100 ng/ml group, which was $(2.24 \pm 0.57)$ times higher compared with the control group;
3. ACE2 agonist DIZE acting on HPMECs under stimulation of LPS injury: (1) did not affect ACE2 protein expression, (2) decreased its LDH release activity, (3) decreased its release of pro-inflammatory factors IL-1β and IL-6, (4) down-regulated LPS-induced increased Ang II release, (5) did not affect the level of Ang-(1-7) release, (6) increased the expression of the Ang-(1-7) receptor MasR, approximately $(1.30 \pm 0.08)$ times of the LPS group, (7) attenuated the phosphorylation level of ERK, approximately $(0.82 \pm 0.10)$ times of the LPS group;
4. ACE2 antagonist MLN-4760 acting on HPMECs under stimulation of LPS injury: (1) decreased ACE2 protein expression, (2) elevated its LDH release activity, (3) promoted the release of the pro-inflammatory factors IL-1β and IL-6, (4) had no effect on the LPS-induced Ang II release induced by LPS, (5) reduced the level of Ang-(1-7) release, (6) reduced the expression of the Ang-(1-7) receptor MasR, approximately $(0.66 \pm 0.07)$ times of the LPS group, (7) attenuated the phosphorylation level of ERK approximately $(0.74 \pm 0.04)$ times of the LPS group.

5. MasR inhibitor A779 acting on HPMECs under stimulation of LPS injury: (1) did not affect ACE2 expression, (2) did not affect Ang II and Ang-(1-7) release induced by LPS, (3) decreased the expression of Ang-(1-7) receptor MasR, approximately ($0.72 \pm 0.13$) times of the LPS group, (4) attenuated the phosphorylation level of ERK, approximately ($0.77 \pm 0.03$) times of the LPS group.
**Conclusions:** The expression of ACE2 was up-regulated in the HPMECs cell injury model induced by LPS. Activation of ACE2 could up-regulate the expression of MasR, reduce the phosphorylation level of ERK and reduce the release of inflammatory factors. It indicated that during the development of ALI/ARDS, ACE2 may act through MasR/ERK signaling pathway. The pathway reduces pulmonary microvascular endothelial cell damage and plays a role in lung protection.

### Optimizing linezolid therapy in critically ill septic adults following high-risk cardiovascular surgery

L. Holub[1], K. Kárpáthi, B. K. Gellért[2], E. Holndonner-Kirst, B. Lakatos[3], B. G. Szabó[3], P. Andreka[4]

*Intensive Care Medicine Experimental* 2024, **12(suppl 1):**001350

**Introduction:** Sepsis-induced pathophysiological changes can result in serious alterations in the pharmacokinetic parameters of antibiotics. Drug exposure is consequently difficult to predict in critically ill septic patients. The latest Surviving Sepsis Campaign guidelines recommend routine therapeutic drug monitoring (TDM) to optimize antibiotic therapy in this patient population. Linezolid is an oxazolidinone antibiotic used to treat infections caused by Gram-positive bacteria. The prevalence of its adverse effects is associated with higher exposure, while suboptimal concentrations can lead to treatment failure and an increased risk of clonal evolution of resistant strains.
**Objectives:** The aim of the study was to determine optimal dosing strategies guided by TDM results among critically ill septic adult patients following high-risk cardiovascular surgery within the intensive care units of a national cardiovascular surgery center.
**Methods:** Consecutive patients receiving empiric or targeted linezolid therapy with TDM guidance were included between April 2022 and March 2024. Blood samples, promptly centrifuged, allowed for the measurement of serum linezolid levels within 24 h using high-performance liquid chromatography with light absorbance detection (HPLC–UV). Trough levels were assessed under intermittent dosing, while random post-steady state samples were collected during continuous infusion.
**Results:** Twenty-six patients (16 men, 10 women) included, from whom a total of 82 samples were taken. Median age was 58 years (interquartile range: 49–68). Target concentration was defined as Cmin: 5–7 mg/l for pathogens with MIC = 2 mg/l with intermittent dosing, while AUC/MIC: 80–120 (area under the plasma concentration–time curve and minimal inhibitory concentration ratio) with continuous infusion. TDM-guided dose adjustments were executed in 20 patients. Optimal linezolid exposure was only achieved with continuous infusion of higher doses (1800–3000 mg/24 h), except for one case. Dose reduction necessitated by clinical improvement could be accomplished in six patients. Serum linezolid levels showed no correlation with kidney function, body mass index (BMI) age, or gender.
**Conclusions:** Standard dosing regimens may fail to provide optimal linezolid exposure among critically ill septic adults following high-risk cardiovascular surgery. Continuous infusion and close monitoring emerge as potential requisites in this population. TDM stands out as a tool in guiding tailored therapeutic strategies, enhancing the precision and efficacy of linezolid therapy.

### Neuromonitoring in UK Intensive Care Units; a survey of practice in 2024

C. O'Hagan[1], A. Williams[1]
[1]Critical Care, Derriford Hospital, Derriford Road, Plymouth, UK, Plymouth, United Kingdom
**Correspondence:** C. O'Hagan
*Intensive Care Medicine Experimental* 2024, **12(suppl 1):**001351

**Introduction:** Multiple modalities exist for neuromonitoring in the unconscious patient with neurological injury1. Where clinical neurological examination is not possible, a combination approach is advocated, previous surveys have highlighted the widespread use of intracranial pressure monitoring in UK ICUs2. Publications highlight the broad range of possible modalities targeting our expanding understanding of cerebral physiology; however, with varied evidence to support their use the uptake of these modalities across the country is likely similarly varied.
**Objectives:** We sought to determine the current state of neuromonitoring in the UK.
**Methods:** Units managing adult patients in the UK were identified using the Neuro Anaesthesia and Critical Care Society (NACCS) list of neuroscience centres. 26 centres were identified in England, Northern Ireland and Wales managing adult traumatic brain injuries. A single page survey was completed by telephone to the departments or link sent via the intensive care medicine trainee WhatsApp network. Remaining departments were contacted via email to the NACCS linkman.
**Results:** All 26 centres responded to the survey. All centres used ICP monitoring with a clear protocol to manage patients in keeping with previous surveys2. All centres reported access to and variable use of electrophysiological testing. Brain tissue oxygenation monitoring PbtO2 was available in 31% (8/26). Transcranial Dopplers in 42% (11/26), Serum biomarkers in 23% (6/24). 4 centres utilised thermal diffusion monitoring. 5 were able to use optic nerve sheath diameter assessment. 1 centre used cerebral microdialysis and a further single unit utilised pressure reactivity monitoring. 6 centres performed assays of serum biomarkers in selected patients.
All units had protocols for management of ICP with a further 7 centres having protocols that incorporated electrophysiology monitoring. 3 of the 11 centres utilising transcranial Dopplers incorporated this into a protocol. 5 centres incorporated brain tissue oxygenation into their standard management protocol with a further centre indicating a protocol was in development at the time of survey. The unit with cerebral microdialysis reported a protocol for management, 1 of the 4 units with thermal diffusion managed according to a protocol. All parameters without a standardised protocol were set on an individual patient basis by a senior clinician when indicated.
**Conclusions:** Across the UK, ICP monitoring and electrophysiology assessment is the most common form of neuromonitoring available to the ICU. All units have a standard protocol for management of ICP variation, with many having protocols incorporating electrophysiology monitoring, transcranial Doppler assessments and brain tissue oxygenation.

***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001353

**Introduction:** Heart transplantation has proven to be an effective treatment for end-stage heart failure, providing a significant improvement in both quality and quantity of life. However, the limitation in the availability of donor organs has been a persistent obstacle. The reintroduction of cardiac donation after circulatory determination of death (DCD) in 2014 has boosted transplant activity by 30%.
This study focuses on evaluating the clinical outcomes of heart transplants performed at Bellvitge University Hospital.
**Objectives:** To evaluate the feasibility of heart donors in controlled asystole (DCD). To analyze the outcomes of heart transplantation with this type of donors.
**Methods:** This is a retrospective unicentric observational study, in a tertiary hospital in Barcelona, from January 2020 to October 2023, of heart donors in DCD as well as their respective transplants. Donor and recipient characteristics were evaluated including variables such as demographic characteristics, ischemia times, duration of extracorporeal circulation (ECC) and clamping, days on mechanical ventilation, ICU stay, post-surgical complications, need for pharmacological or mechanical support, and survival at ICU and hospital discharge.
**Results:** Seventeen donors were included, with a mean age of 39.4 years (±11.4), 70.6% were men. The most frequent cause of life support limitation was hemorrhagic stroke 23.5%, followed by subarachnoid hemorrhage (SAH) 17.6%. The most frequent cause among recipients was non-ischemic cardiomyopathy with 52.9%, with 93.3% being elective transplants. The mean cold ischemia time was 115.33 min (±39.5) and ECC time 96.27 min (±18.74). The mean ICU stay was 10.40 days (±10.35). As complications, 23.5% presented primary graft dysfunction and 47.1% acute renal failure. Survival was 100% at 90 days.
**Conclusions:** DCD donors significantly expand heart transplantation, showing comparable results to brain death donors. This option can address the growing demand for heart donors. Further investigation is needed into the effects of DCD on organ quality and functionality.

**Correspondence:** E. Tsigou
***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001354

**Introduction:** Severe community and hospital-acquired lower respiratory tract infections are associated with high morbidity and mortality. Delay or failure to identify the causative pathogen further worsens the prognosis, and on the other hand, inappropriate antibiotic use contributes to antimicrobial resistance and augments cost.
The BioFire FilmArray Pneumonia Panel (BioFire PN; BioMérieux) is a multiplex polymerase chain reaction (PCR) assay that analyzes respiratory specimens for the presence of bacteria, viruses, and genetic markers of antimicrobial resistance within some hours.
**Objectives:** To evaluate the performance of the BioFire PN in the pathogen recognition of lower respiratory tract infections of Intensive Care Unit (ICU) patients (pts), and to compare it with conventional microbiological methods.
**Methods:** All BioFire PN lower respiratory samples (bronchial aspirates, BAL) received from ICU pts with lower respiratory tract infections (community-acquired pneumonia—CAP, hospital-acquired pneumonia—HAP, ventilator-associated pneumonia—VAP, and tracheobronchitis) in a period of 18 months were retrospectively analyzed. Results were compared with simultaneously received cultures' results and with clinical indices.
**Results:** The analysis included 79 BioFire PN samples from 52 pts [34 men, age 69 (25–88) years, APACHE II score 18 ± 5.82, LOS: 35.60 ± 24.91 days, survival 23.07%]. Of the 79 evaluations, there were 23 cases of CAP and 56 cases of nosocomial infections (HAP, VAP, tracheobronchitis) (Table 1).

**Table 1 (abstract 001354)** Evaluation of filmarray pneumonia panel results

| | SOFA | Septic shock | FA positive | Culture positive | Methods agreement* | Improvement | Antibiotics' change* | Antibiotics' de-escalation |
|---|---|---|---|---|---|---|---|---|
| CAP ($n=23$) | 10.43 ± 2.71 | 17 (73.9%) | 20 (86.96%) | 5 (21.74%) | 7 (35%) | 86.96% | 14 (70%) | 5 (35.71%) |
| Nosocomial infections ($n=56$) | 8 (3–18) | 35 (62.5%) | 38 (67.86%) | 13 (23.21%) | 24 (63.16%) | 75% | 25 (65.79%) | 5 20%) |

*antibiotics' de-escalation included.

In the 23 CAP infections, BioFire PN detected both a virus and a bacterium in 11 cases, a single virus in 6 cases, a single bacterium in 2 cases, and polybacterial etiology in 1 case.
In the 56 nosocomial infections, BioFire PN detected a single bacterium in 15 cases, polybacterial etiology in 13 cases, both a virus and one or more bacteria in 7 cases, and a single virus in 3 cases.
Results of BioFire PN were available within 6–12 h, even though samples were transmitted to another facility, whereas positive cultures were completed in 24–48 h, and another 24 h were needed for the susceptibility testing.
**Conclusions:** FilmArray Pneumonia Panel compared to cultures showed a high sensitivity for the identification of pathogens in cases of lower respiratory tract infections in critically ill pts, especially for severe community-acquired pneumonia. The rapid results allowed for antibiotics' de-escalation within 12 h.

**Introduction:** Potassium is a crucial electrolyte involved in numerous physiological processes. Hyperkalemia is a common electrolyte imbalance encountered in critically ill patients, with potential implications for adverse outcomes itself. Due to this recognized link (1), levels of potassium are frequently considered in severity illness scores, such as the Acute Physiology and Chronic Health Evaluation II (APACHE II), which attempt to predict the risk of mortality based on several parameters upon admission to Intensive Care Units (ICUs). Some studies have indicated an independent correlation between hyperkalemia upon ICU admission and in-hospital mortality, although a causal relation could not be demonstrated (2,3,4).
**Objectives:** We aim to investigate the correlation between hyperkalemia at ICU admission and both ICU and in-hospital mortality, through a retrospective study.
**Methods:** A retrospective analysis was conducted on data collected from electronic medical records of patients admitted to our ICU from 2022 to 2024. Patients were divided in two groups based on their serum potassium levels at admission: hyperkalemia (potassium > 5.0 mmol/L) and non-hyperkalemia (potassium ≤ 5.0 mmol/L). The statistical analysis involved comparing the baseline demographics, admission characteristics and length of stay of survivors and non-survivors within each group. This comparison was conducted using the Chi-square ($\chi 2$) test for categorical variables and Mann–Whitney U-test for continuous values, to evaluate proportional differences in outcomes. In addition, we performed a logistic regression analysis, adjusting for potential confounders such as age, presence of septic shock or ketoacidosis upon admission, APACHE II score, and the need for Renal Replacement Therapy (RRT) during ICU stay for both ICU mortality and in-hospital mortality. Odds ratios (OR) were calculated with 95% confidence intervals. Statistical significance was set at a predetermined P value of < 0.05.
**Results:** In this study, 1065 patients were enrolled, of whom 17.7% ($N=189$) presented hyperkalemia at admission. Among the hyperkalemia group, 69.3% were male ($N=131$) with an average age of 66.1 ± 17 years, while in the non-hyperkalemia group, 61.2% were male ($N=536$) with an average age of 64.1 ± 17 years. The mean APACHE II score for the hyperkalemic and non-hyperkalemic groups was 20.8 ± 11 points and 17.9 ± 12 points, respectively ($p<0.001$). The average ICU stay was 5.9 ± 6 days for hyperkalemic patients and 7.3 ± 9 days for the others (p 0.042), while the in-hospital stay was

16.1 ± 18 for hyperkalemic patients and 18.6 ± 23 days for others (p 0.178). Septic shock at admission was present in 33.3% ($N = 63$) of the hyperkalemic patients and 28.1% ($N = 246$) of the others (χ2 2.081, p 0.149), while ketoacidosis was present in 3.7% ($N = 7$) of hyperkalemic patients and 2.9% ($N = 25$) of the others (χ2 0.38, p 0.535). The need for RRT was 31.2% ($N = 59$) in the hyperkalemia group and 9.7% ($N = 85$) in the non-hyperkalemia group (χ2 61.5, $p < 0.001$). ICU mortality rate was 19.6% ($N = 37$) and 16.8% ($N = 147$) for hyperkalemic and non-hyperkalemic patients, respectively (χ2 0.852, df 1, OR 0.19, p 0.356), while in-hospital mortality rates were 32.8% ($N = 62$) and 23.3% ($N = 204$) for hyperkalemic and non-hyperkalemic patients, respectively (χ2 7.514, df 1, OR 0.48, p 0.006). The logistic regression analysis revealed a weak association between hyperkalemia at admission and ICU mortality (OR 0.90, df 1, p 0.647)—Table 1—but a slightly stronger association with in-hospital mortality (OR 1.29, df 1, p 0.163)—Table 2. Notably, more significant predictors of mortality in this sample were the need for RRT ($p < 0.001$; p 0.002), septic shock (p 0.053; p 0.461), APACHE II score (p 0.117; p 0.011), and age (both $p < 0.001$).

**Conclusions:** Hyperkalemic patients showed higher APACHE II scores, longer ICU stays, and more need for RRT. Mortality rates were higher in both ICU and in-hospital settings, but only with significance in the latter. However, establishing a conclusive correlation between hyperkalemia and mortality was not possible due to the influence of other confounding variables.

Contrary to expectations, hyperkalemia at admission did not correlate significantly with ICU mortality. However, a subtle link with in-hospital mortality suggests its impact on longer term outcomes. More research is needed to confirm and understand these findings better.

**Introduction:** The prevalence of difficult to treat infections due to Gram-negative bacteria has increased over recent years. Treatment options are limited while failure of response to antibiotics is associated with high morbidity and mortality rates. Meropenem/vaborbactam is a novel antibiotic recently approved for the treatment of Gram-negative infections in adults with limited treatment options.

**Methods:** This is a single-center retrospective observational study in ICU patients who received meropenem/vaborbactam for suspected or confirmed Gram-negative infections. Patients were categorized according to the source of infection. The variables measured were the duration of treatment, the survival rate, the response to treatment with meropenem/vaborbactam and the adverse effects of meropenem/vaborbactam for the total of patients and for every group, respectively. The response to treatment with meropenem/vaborbactam was defined as clinical and/or laboratory improvement.

**Results:** In our study, 38 ICU patients were included. The patients were categorized into the four following groups: Group A = Respiratory Tract Infections (25 out of 38, 66%), Group B = Bloodstream Infections (6 out of 38, 16%), Group C = Abdominal Infections (5 out of 38, 13%) and Group D = Soft Tissue Infections (2 out of 38, 5%). The average duration of therapy for the total of 38 ICU patients was 9 days. 63% (24 out of 38) responded to treatment. The overall survival rate was 58% (22 out of 38). Regarding the subgroups, for Group A, the average duration of therapy was 9 days. 56% (14 out of 25) responded to treatment and the survival rate was 60% (15 out of 25). For Group B, the average duration of therapy was 8 days. 100% (6 out of 6) responded to treatment and the survival rate was 67% (4 out of 6). For Group C, the average duration of therapy was 14 days. 60% (3 out of 5) responded to treatment and the survival rate was 80% (4 out of 5). For Group D, the average duration of therapy was 5 days. 100% (2 out of 2) responded to treatment and the survival rate was 0% (0 out of 2). 16% (6 out of 38) from the total of patients needed renal replacement therapy due to severe sepsis or septic shock which was not associated with the administration of meropenem/vaborbactam. Only 5% (2 out

of 38) of the patients had minor adverse effects (raise in LFTs) related with the treatment with meropenem/vaborbactam. Major adverse effects were not detected.
**Conclusions:** Our results support that meropenem/vaborbactam may be an effective and safe option for difficult to treat Gram-negative infections. Further studies should be performed to determine the optimal use of this important new antibiotic in the treatment of Gram-negative infections.

### Meropenem/vaborbactam as an alternative therapeutic option in severe, complicated Gram negative infections in critically ill patients. A single-center experience

G. Gkogkos[1], G. Katsikaki[1], E. Kerezidou[1], N. Taouktsi[1], D. Ntantos[1], E. Lazoudi[1], S. Papoti[1], C. Iasonidou[1]

*Intensive Care Medicine Experimental* 2024, **12(suppl 1):**001360

**Introduction:** Increasing bacterial resistance and failure to antibiotic treatment, resulting in detrimental outcomes, has raised great concern worldwide. Meropenem/vaborbactam is a new alternative agent for severe, complicated Gram negative infections. Currently, there are limited data in clinical practice for the efficacy and safety of meropenem/vaborbactam, especially in critically ill patients.
**Methods:** We aimed to report our experience with the use of meropenem/vaborbactam in clinical practice for the treatment of Gram-negative infections in patients with insufficient response to previously administered antibiotics. All the enrolled patients were being administered broad-spectrum antibiotics (monotherapy or combination therapy) for suspected or confirmed Gram-negative infection and were switched to treatment with meropenem/vaborbactam due to no response or clinical and/or laboratory deterioration. Clinical deterioration was defined as new onset of fever, hemodynamic instability or worsening of respiratory status due to infection. Laboratory deterioration was defined by white blood cell count (WBCs) < 4000 or > 12,000, presepsin > 500 and procalcitonin (PCT) > 0.5. The measured variables were the values of WBCs, presepsin and PCT at the start of treatment with meropenem/vaborbactam, the mean duration of therapy, the response to treatment with meropenem/vaborbactam, the overall survival rate during their stay in the ICU and the 30-day mortality rate. The response to treatment was defined as clinical and/or laboratory improvement.
**Results:** In our study, 30 ICU patients were included. All the patients experienced clinical deterioration which was combined with abnormal inflammatory markers. 67% (20 out of 30) had pathological WBCs, 83% (25 out of 30) had pathological presepsin and 57% (17 out of 30) had pathological PCT at the start of treatment with meropenem/vaborbactam. The mean duration of therapy was 9 days. 67% (20 out of 30) responded to treatment with meropenem/vaborbactam. The overall survival rate was 67% (20 out of 30) and the 30-day mortality rate was also 67% (20 out of 30).
**Conclusions:** Our experience supports the use of meropenem/vaborbactam in clinical practice as a reasonable alternative for complicated, difficult to treat Gram-negative infections.

### The impact of the CERTAIN Clinical Decision Support Tool for structured ICU admission and rounding is sex independent—a secondary analysis of CERTAIN

P. Swart[1], A. Tekin[2], Y. Dong[3], M. Vukoja[4], R. Kashyap[5], O. Gajic[6], M. Malinchoc[7], F. Paulus[1], M. Schultz[8]

**Correspondence:** P. Swart
*Intensive Care Medicine Experimental* 2024, **12(suppl 1):**001363

**Introduction:** Numerous studies have highlighted the presence of sex inequity in critical care provision. The Implementation of the 'Checklist for Early Recognition and Treatment of Acute Illness and Injury' (CERTAIN) decision support tool for structured ICU admission and rounding was associated with an increased adherence to best care practices(1). It is uncertain whether implementation of CERTAIN had comparable effects in females and males.
**Objectives:** We determined whether the effects of implementation of CERTAIN would be different between the sexes. In a subgroup analysis, we also assessed the impact of implementation in females and males in high income (HIC) and low- and middle-income countries (LMIC).
**Methods:** This is a post hoc analysis of CERTAIN, a conveniently sized prospective multinational before–after quality-improvement study in 34 ICUs in 5 HIC and 10 LMIC. We compared incidence rates of omission of delivery of 10 best care practices, including deep vein thrombosis and peptic ulcer prophylaxis, head of bed elevation, daily oral care, spontaneous breathing trials, family conferences, assessment of need for central lines and urinary catheters, and prescription of antimicrobials and sedation, between sexes, before and after implementation of the decision support tool. In addition, we determined whether sex differences, if present, existed amongst HIC versus LMIC. The sexes were compared with respect to these best care practices using Poisson regression. Then, to adjust for a center effect, the incidence rate ratio was calculated with the center modeled as a random effect in a generalized linear mixed model with a log link function.
**Results:** The CERTAIN study comprised a total of 4,256 patients, with 588 females and 1,169 males before implementation of the decision support tool, and 859 females and 1,640 males after its implementation. Females were older, had a lower median body weight but were more often obese. Females more often had a history of hypothyroidism, rheumatoid arthritis, and collagen vascular disease; males more

often had a history of alcohol abuse and liver disease. Compared to patients in HIC, patients in LMIC were younger, and had a lower median SOFA score. Patients in HIC more often had a history of alcohol abuse.
Overall, there was no notable difference in care between sexes, both before nor after implementation **(**Figure 1). Females and males experienced equal benefits from the checklist implementation (Figure 2). The implementation of the checklist yielded consistent outcomes across various geo-economic settings.
**Conclusions:** The impact of a web-based clinical decision support tool for structured ICU admission and rounding on nonadherence to best care practices showed minimal variation between sexes and benefitted both female and male patients. This observation remained consistent across ICUs in various geo-economic areas and indicates that a systematic checklist is feasible in resource-limited settings.

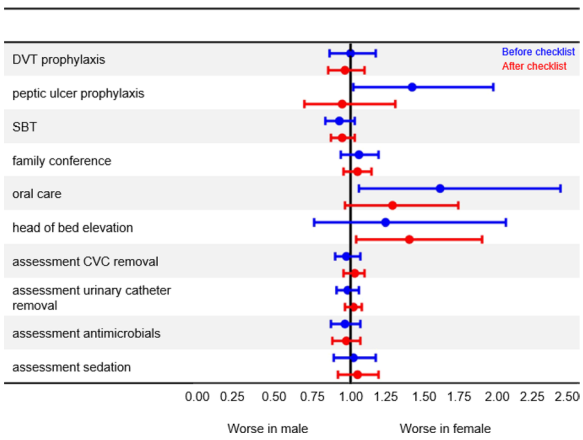

**Fig. 1 (abstract 001363)** The incidence rates of nonadherence to daily care processes between the sexes—LMIC + HIC. CVC = central venous catheter; DVT = deep vein thrombosis; HIC = high-income countries; LMIC = low- and middle-income countries
Checklist for Early Recognition and Treatment of Acute Illness and Injury (CERTAIN).
An event refers to a non-adherence to an evidence-based daily care process.
Adjusted for Center Effect Incident Rate Ratios. In this Figure, the blue whisker compares the incident rates of events between female versus male patients before the checklist and the red line compares the incident rates of events after the checklist.

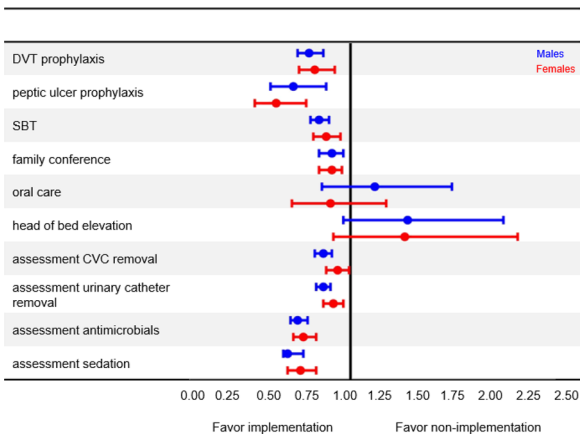

**Fig. 2 (abstract 001363)** The incidence rates of nonadherence to daily care processes before versus after the implementation. CVC = central venous catheter; DVT = deep vein thrombosis; HIC = high-income countries; LMIC = low- and middle-income countries
Checklist for Early Recognition and Treatment of Acute Illness and Injury (CERTAIN).
Adjusted for Center Effect Incident Rate Ratios. In this Figure, the blue whisker compares the incident rates of events between before versus after the checklist in male patients and the red line compares the incident rates of events in female patients.

### Ventilatory response to metabolic acid–base disorders: a single equation to predict arterial PCO2 from standard base excess

***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001367

**Introduction:** Metabolic acid–base disorders trigger a secondary respiratory response to restore a physiologic pH. Several equations have been proposed to predict the compensatory PCO2 from actual bicarbonate (HCO3-): a relevant difference between the expected and the actual PCO2 might suggest a concomitant respiratory disorder. These equations have some limitations: Winters' formula, commonly adopted for metabolic acidosis (PCO2 = 1.5*HCO3- + 8), derives from only 67 children; most studies focus separately either on moderate (pH > 7.1) or severe acidosis; data on metabolic alkalosis are very limited; the proposed equations rely on HCO3-, a PCO2-dependent variable, as marker of metabolic acid–base disorders.
**Objectives:** Aim of our study was to describe the respiratory compensation to metabolic acid–base disorders in a continuum from acidosis to alkalosis. We hypothesized that a single equation, using standard base excess (SBE), a PCO2-independent marker of metabolic acid–base disorder, would be able to describe the ventilatory response.

**Methods:** English literature published up to March 2024 was reviewed. Non-sedated, spontaneously breathing humans, aged > 2 months, admitted to the hospital with a metabolic acid–base disorder, or undergoing an experimental study on the topic were enrolled. Control subjects of the selected papers were included. Individual or semi-aggregated data from couples of PCO2-HCO3- or PCO2-pH from arterial/arterialized capillary blood were collected from tables or Figures (https://automeris.io/WebPlotDigitizer.html). A non-carbonic buffer power of 16.2 mmol/L was assumed to calculate SBE.
**Results:** A total of 1619 patients (1259 acidotic, 332 alkalotic, 28 controls) were selected from 32 publications. The observed ranges of pH, HCO3-, BE, and PCO2 were 6.58 to 7.73, 1.1 to 94 mmol/L, -36.5 to 74.1 mmol/L, and 4 to 86 mmHg, respectively. A strong correlation was observed between SBE and PCO2 (Figure), both using a single quadratic (PCO2 = -0.004 * (SBE)2 + 0.8*SBE + 38.1, r2 = 0.85, $p < 0.001$) or a linear regression (PCO2 = 0.8*SBE + 37.2, r2 = 0.84, $p < 0.001$).
**Conclusions:** A single equation is able to predict accurately from SBE the expected compensatory PCO2 over the entire spectrum of metabolic acid–base derangements. The linear simplification could be a helpful bedside tool for the interpretation of complex acid–base disorders.

***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001368

**Introduction:** Intensive Care Unit (ICU) survivors are at increased risk of developing persistent pain, post-traumatic stress disorder (PTSD), while they may also experience impaired health-related quality of life (HRQoL). However, few studies assessed pain, PTSD, and HRQoL at multiple time points after ICU discharge.
**Objectives:** To assess the prevalence of self-reported pain and PTSD symptoms, and HRQoL among ICU survivors at one, three, six and 12 months following ICU discharge.
**Methods:** This is a prospective, observational study of discharged ICU patients from a 12-bed mixed ICU. The study was conducted from November 2018 to July 2021 and survivors were followed up at four time points: 1st month (T1), 3rd month (T2), 6th month (T3), and 12th month (T4) post ICU discharge. The instruments used were the Numeric Rating Scale (NRS) [scale range: 1–10] to assess pain, the Davidson Trauma Scale (DTS) [scale range: 0–68] to assess frequency of PTSD symptoms and the 36-Item Short Form Survey version 2 (SF-36v2) to assess the eight domains of HRQoL. Variance analysis for repeated measures was used to identify changes of variables over time.
**Results:** 64 out of 87 survivors consented to participate at T1. Due to death or refusal to continue to participate to the study, 59 survivors were enrolled at T2, 42 at T3 and 33 at T4. Mean pain scores were 5.3 at T1, 3.7 at T2, 2.9 at T3, and 2.0 at T4 ($p < 0.001$). NRS > 3, indicative of moderate to severe pain, was reported from 92.2% of survivors at T1, 76.3% at T2, 61.9% at T3 and 39.4% at T4. DTS mean scores were 49.1, 42.1, 29.2 and 20.5 at T1, T2, T3 and T4, respectively ($p < 0.001$). HRQoL was improved in all domains, from T1 to T4 follow-up period ($p < 0.001$).
**Conclusions:** Despite the fact that there was a decrease in pain and PTSD symptoms prevalence over time, even at 12 months post-ICU discharge, ICU survivors still suffered from them. HRQoL was impaired after critical illness but findings showed a statistically significant improvement over the follow-up period. This study underscores the importance of ongoing monitoring and support, as well as the potential for interventions to improve ICU survivors' long-term outcomes and quality of life.

**Introduction:** Intravenous (IV) sedation and opioids are administered to intensive care unit (ICU) patients for anxiety, pain, and somnolence in mechanical ventilation. However, prolonged exposure to high medication doses places patients at significant risk of IWS upon abrupt cessation or rapid tapering of medications.1–3 IWS encompasses a combination of autonomic dysregulation, central nervous system arousal, and gastro-intestinal symptoms. It is associated with adverse clinical outcomes that include prolonged mechanical ventilation, psychological distress, longer hospital and ICU stay, higher morbidity, and elevated healthcare costs.4,5 There are increasing reports of IWS in

ICU adults, but how it is recognised by healthcare professionals is less established.
**Objectives:** To determine ICU healthcare professionals' perspective on incidence, detection and research in IWS in IV sedation and opioid use in adult ICU.
**Methods:** The survey was registered as a service evaluation without the need for ethics. An online survey was piloted (Survey Monkey), revised and distributed via various professional societies of Irish and UK ICU community, addiction psychiatrists and social media. The survey was open for 16 weeks from 5 February 2023 with reminders sent for completion. Data were analysed using descriptive statistics.
**Results:** 246 responses were received from ICU healthcare professionals including nurses 32% (79/246); pharmacists 30% (75/246); medical doctors (consultant-level) 27% (66/246); medical (other) 7% (17/246); allied health professionals 2% (5/246) and other 2% (4/246). Overall, 90% (221/246) indicated that IWS was a clinically important issue for adults in ICU and 80% (198/246) felt that a validated IWS screening tool would be useful for clinical practice. 24% (59/246) reported they were familiar with strategies for prevention and/or treatment of IWS and 13% (31/246) had IWS guidelines available in their ICU. 89% (218/246) stated that there is a need to improve clinical guidance for identification, prevention and treatment of IWS in adult ICUs. With 90% (220/246) reporting that more research is needed to understand the incidence and impact of IWS in adult ICUs.
**Conclusions:** ICU professionals surveyed indicated that IWS was very common in their clinical practice and a majority reported the need for further guidance to identify and treat IWS. The absence of IWS screening tools, coupled with a lack of understanding regarding prevalence and treatment strategies, indicates a significant gap in clinical knowledge. Given the clinical importance, we strongly recommend further research and development to bridge these critical gaps and provide clinical guidelines.

**Introduction:** Unphysiological alveolar stretch, associated with mechanical ventilation, can instigate lung inflammation1 and may predispose the lungs to postoperative pulmonary complications (PPCs). This deleterious outcome occurs in up to 33% of major operations2 but the underlying mechanism is poorly understood.
There is increasing evidence supporting the role of microvesicles (MVs), which are released following cellular injury, in the propagation of various lung pathologies3,4, acting as efficient mediators of cellular communication during inflammation.
**Objectives:** We aimed to investigate the role of MVs during the pathophysiology of PPCs by assessing: 1) any correlation between intra-alveolar MVs with markers of lung inflammation, lung injury and clinical outcome, and 2) the bioactivity of in vivo derived MVs.
**Methods:** Oesophagectomy patients, who undergo prolonged periods of one-lung ventilation (OLV) were used as a human model of alveolar stretch. Serial bronchoalveolar lavage (BAL) samples were collected from both lungs at clinically relevant intra-operative time points. Gastrectomy patients undergoing prolonged two-lung ventilation (TLV) acted as controls. Ethical approval was granted (REC: 21/PR/1554).
BAL was analysed for MV subtypes using our established flow cytometry protocols and correlated with BAL cell numbers (flow cytometry), IL-6 and IL-8 (ELISA), total protein (Qubit) and perioperative clinical data.
BAL NMVs after OLV, isolated using a positive bead isolation technique, were added to an in vitro alveolar model, a co-culture of human alveolar epithelial cells (HAECs) and peripheral blood mononuclear cells. After four hours of incubation, cell adhesion molecules, markers of epithelial cell inflammation, were assessed (flow cytometry).
**Results:** Forty-two oesophagectomy and seven gastrectomy patients were recruited. OLV caused an increase in all MV subtypes in the ventilated lung but not the non-ventilated lung; this was most notable for neutrophil-derived MVs (NMVs): ventilated lung (220 v 1062 NMVs/ul, $p<0.0001$) vs non-ventilated lung (331 v 288 NMV/ul, $p=0.515$). NMVs correlated strongly with BAL protein ($r=0.817$, $p<0.0001$), IL-8 ($r=0.721$, $p<0.0001$) and IL-6 ($r=0.505$, $p=0.0085$). NMVs in the ventilated lung after OLV were significantly greater in patients who had a PPC compared to those who didn't (3667 v 488 NMV/ul, $p=0.0052$) yet neutrophils in either lung following OLV did not correlate with PPCs. Protective TLV in oesophagectomy or gastrectomy patients did not cause a significant increase in NMVs.
In vitro, NMVs caused significant HAEC ICAM upregulation compared to controls ($p=0.0492$).
**Conclusions:** We have demonstrated that unphysiological alveolar stretch associated with OLV causes profound NMV release which correlates strongly with markers of lung injury/inflammation and clinical outcomes. Importantly, NMVs produced following OLV had significant bioactivity causing HAEC inflammation in vitro, further evidence of the important role of NMVs in the pathophysiology of PPCs.

**Introduction:***Streptococcuspyogenes*, also known as Group A Streptococcus (GAS), is a common human pathogen responsible for a wide range of infections, from mild pharyngitis to severe invasive diseases. Infections caused by *S. pyogenes* can lead to significant morbidity and mortality, particularly when patients require admission to the intensive care unit (ICU). Understanding the clinical characteristics, management strategies, and outcomes of patients admitted to the ICU with *S. pyogenes* infections is crucial for optimizing patient care and outcomes.
**Objectives:** This study aims to analyze the clinical features, treatment modalities, and outcomes of patients admitted to the ICU with *Streptococcus pyogenes* infections.
**Methods:** We conducted a retrospective analysis of 12 patients who were admitted to the ICU with confirmed infections caused by *Streptococcus pyogenes*. Data on clinical manifestations, treatment strategies, and outcomes were systematically collected and analyzed.
**Results:** In this detailed analysis, we included a cohort of 12 patients who were admitted to the Intensive Care Unit (ICU) due to infections caused by *Streptococcus pyogenes*. The median age among the patients was 48.25 years. The majority of these patients, approximately 58.33%, were male, indicating a slight gender disparity in the incidence of these severe infections.
The clinical presentation of these patients varied, but several common symptoms were identified. These included hypotension, fever, coagulopathy, and acute renal failure. A significant proportion, 83.33%, of these patients developed severe complications, manifesting as either severe sepsis or septic shock, highlighting the critical nature of these infections.
Upon conducting microbiological evaluations, we observed a notable resistance pattern; there was a high rate of resistance to macrolides, which complicates treatment options. In terms of management strategies, immunoglobulin therapy was administered to 33% of the patients, reflecting its use as a treatment modality in severe cases.
The mortality statistics from this cohort are particularly concerning, with an overall mortality rate of 33%. A deeper dive into the mortality data revealed that in 75% of the cases where the patient deceased, there was a failure in controlling the primary infection site, suggesting a potential area for clinical improvement.
This analysis underscores the severity of *Streptococcus pyogenes* infections in ICU settings and the challenges in managing these cases, particularly with antibiotic resistance and the critical need for effective focus control to improve patient outcomes.
**Conclusions:** This study highlights the critical severity and complex management challenges associated with *Streptococcus pyogenes* infections in ICU patients. The high mortality rate, predominantly due to inadequate control of the infection site, and the significant prevalence of macrolide resistance demand urgent attention. These findings underscore the necessity for enhanced diagnostic strategies, more aggressive management approaches, and the development of new therapeutic modalities to effectively tackle the resistance patterns. Implementing these improvements is essential for reducing mortality and improving outcomes in this vulnerable patient population.

**Introduction:** Acute kidney injury (AKI) is a common complication in critically ill with adverse outcomes. However, the absence of a biomarker in kidney injury; similar to troponin in cardiac patients often leads to delay in predicting and promptly identifying AKI. A combination of clinical risk factors and serum creatinine changes could potentially help in early identification of patients at risk of AKI. In addition, a renal anginal index (RAI) has been described; taking into account the creatinine score as well as the patient condition. These, however, have not been extensively studied in Indian population.
**Objectives:** The study evaluated the efficacy of combining smaller changes in serum creatinine with clinical risk factors in predicting the risk of AKI in critically ill Indian population. The performance of RAI was also evaluated.
**Methods:** This was a prospective comparative validity study conducted in a tertiary medical intensive care unit. Patients were divided into 3 groups—very high risk, high risk and moderate risk according to their clinical risk factors. The change in serum creatinine was assessed at 24 h; those at high risk of developing AKI were identified based on an early increase in serum creatinine of 0.1–0.4 mg/dl in 24 h. Renal anginal index (RAI) based on the creatinine and condition score was calculated at 24 h of ICU admission. The creatinine score was determined by the difference in serum creatinine in the first 24 h of ICU admission. The condition score was calculated based on presence of risk factors like requirement of ventilator or vasopressor therapy, diabetes mellitus and ICU admission. The RAI score (1) was calculated as the worst condition score multiplied by the creatinine score to give

values ranging from 1, 2, 3, 4, 6, 8, 10, 12, 24, and 40. These patients were monitored for the development of severe AKI (KDIGO stage 2/3) for the period of ICU stay up to a maximum of 7 days.
**Results:** Out of 90 patients, 44 had early creatinine elevation; of which 23 (52%) progressed to severe AKI. The remaining 46 patients who did not have creatinine elevation at 24 h did not progress to severe AKI ($p < 0.001$). The RAI (Renal Anginal index) cutoff was calculated to be 7 for predicting the risk of AKI. The receiver operating curve (ROC) of RAI had an area under the curve (AUC) of 0.958, p value < 0.001, sensitivity of 100% and specificity of 80.6%. The mean RAI for patients who did not have creatinine elevation was $4.2 \pm 2.1$, while it was $22.5 \pm 12.6$ in those who had creatinine elevation ($p < 0.001$). 13 out of the 23 patients with severe AKI required RRT. Mortality was also significantly higher in the patients who progressed to severe AKI (65% vs 32%).
**Conclusions:** Combining clinical risk factors with smaller changes in serum creatinine could accurately predict the risk of developing severe AKI in critically ill. In addition, a renal anginal index of 7 at 24 h of ICU admission could reliably predict the risk of developing AKI.

| Creatinine | Score |
|---|---|
| <0.1 mg/dl | 1 |
| ≥ 0.1 mg/dl | 2 |
| ≥ 0.3 mg/dl | 4 |
| ≥ 0.4 mg/dl | 8 |

✖

| Condition | Score |
|---|---|
| ICU admission | 1 |
| Diabetes Mellitus | 3 |
| Vasopressors/Ventilation | 5 |

Renal anginal index (Reference 1)

**Classification of Risk factors**

| | | |
|---|---|---|
| Acute | Chronic major | Chronic minor |
| Hypotension | Advanced age >70 years | Hypertension |
| High risk surgery | Diabetes Mellitus | Morbid obesity |
| Nephrotoxin exposure | Cardiovascular disease | Hyperbilirubinemia |
| Sepsis | Chronic Kidney Disease | Cerebrovascular accident |
| | | Cancer |

**Classification into hazard tiers**

Hazard tier 1 - Very High risk
*Patients with septic shock or*
*Patients receiving vasopressors and mechanical ventilation*

Hazard Tier 2 – High Risk
*1 acute risk factor +1 chronic major risk factor*
*1 acute risk factor + 2 chronic minor risk factor s*
*2 acute risk factors*

Hazard Tier 3 – Moderate Risk
*1 chronic major risk factor or 1 acute risk factor*
*Multiple chronic major and minor risk factors without acute risk factors*

Definition of Creatinine elevation in each hazard tier
Hazard tier 1 (Very High Risk) – increase of 0.1 mg/dl
Hazard tier 2 (High Risk) Increase of 0.3 mg/dl
Hazard Tier 3 (Moderate risk) – Increase of 0.4 mg/dl

*Adapted from reference 3

Clinical risk factors and hazard tiers

***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001377

**Introduction:** Neutrophil-to-lymphocyte ratio (NLR) is a marker of the inflammatory systemic response that has been studied as prognostic biomarker in different pathologies. A few studies have taken interest in its use in polytrauma patients.
**Objectives:** To study the interest of NLR in predicting mortality in polytrauma patients admitted in the intensive care unit (ICU).
**Methods:** It was a retrospective study including polytrauma patients admitted to the medical ICU of Zaghouan's regional hospital in Tunisia between January 2019 and December 2021. Demographic, clinical and evolutionary data were collected. The NLR was calculated at Day 1, Day 2 and Day 7 of care. Two groups were individualized: G1 = Survivors and G2 = Deceased. The correlation between the ratio and mortality was investigated using logistic regression.
**Results:** Fifty patients were included: 30 survivors (G1) and 20 deceased (G2). Mean age was $42.7 \pm 18.8$ years with a gender ratio of 9. Median Injury Severity Score (ISS) was 27 [17–175]. Initial injury assessment revealed cranial trauma in 92% of patients, thoracic trauma in 70%, and abdominal trauma in 44%. Orotracheal intubation was indicated in 74% of cases, catecholamine use in 50% of cases, and urgent surgical intervention in 20% of cases. Healthcare-associated infections were noted in 40% of cases. The overall in-hospital mortality rate was 40% with a median length of ICU stay of 13 days [2–64].
Comparing NLRs at admission, Day 3, and Day 7, a significant prediction of mortality was observed for Day 1 (OR = 27.5; 95% CI [1.48–509.1]; $p = 0.026$) and Day 3 (OR = 122; 95% CI [2–7360]; $p = 0.022$), but not for Day 7 ($p = 0.243$). ROC curve analysis (Figure 1) allowed deduction of mortality prediction cutoffs: RNL1 at 2.8 (sensitivity 80%, specificity 57%) and RNL3 at 6.5 (sensitivity 80%, specificity 64.3%).
**Conclusions:** The analysis of neutrophil-to-lymphocyte ratios at Day 1 and Day 3 of hospitalization allowed for the prediction of mortality in severely polytraumatized patients.

*Intensive Care Medicine Experimental* 2024, **12(suppl 1):**001380

**Introduction:** Respiratory muscles may influence in the occurrence of non-invasive mechanical ventilation (NIV) failure. Bioimpedance analysis (BIA) parameters, which measure body composition (e.g., muscle body composition), have been associated with outcomes in critically ill patients.
**Objectives:** Evaluate the impact of BIA parameters on NIV failure in a cohort of patients with hypoxemic acute respiratory failure due to COVID-19.
**Methods:** This is an observational study in patients with acute respiratory failure in the intensive care units (ICU) of our hospital. We performed BIA during the first 24 h of NIV. Patient characteristics, severity scores, HACOR score, NIV parameters and gas exchange values together with BIA values were included in a database for analysis. We tested the association of BIA values, such as phase angle (PhA), with NIV failure. Univariate and multivariate analysis were performed using SPSS 25.0.
**Results:** We included 74 patients and mortality was 32.4% (24). Mean age was 61.5 ± 12.1 years, the BMI was 31 ± 7 kg·m − 2 and 78.4% (58) were men. 43 patients (58.1%) required tracheal intubation during NIV support with a mean duration of 5.2 ± 4.9 days from the start of NIV to tracheal intubation. We found no differences in the univariate analysis between the patients who required intubation and those who did not, except for a trend towards lower PhA in the intubated patients (4.6 ± 1.2 vs 5.00 ± 1.1; $P = 0.09$). This trend towards a higher incidence of NIV failure with a lower PhA was also observed in the multivariate analysis (hazard ratio: 0.345; 95% CI: 0.113–1.0.48; $P = 0.06$).
**Conclusions:** We found that BIA parameters, such as PhA, related with body composition may be associated with NIV failure. We hypothesized this may be related with baseline metabolic-nutritional status, which may be ultimately reflected by body composition.

**Topic:** Acute respiratory failure and mechanical ventilation

**Introduction:** Circadian rhythms are intrinsic timing mechanisms that allow adaptation to cyclical changes in the environment. Some studies suggest that circadian rhythms may influence the progression of a variety of diseases, such as the efficacy and toxicity of drugs used as well as the influence on mortality. Thus, disrupted circadian rhythms may increase the severity and consequences of stroke, while readjustment of circadian clock machinery may accelerate recovery from stroke. Temporal pattern of stroke events occurs in humans where both ischemic and hemorrhagic strokes have a bimodal pattern with the major and minor peak of events in the morning and evening, respectively. Morning strokes are more likely to be fatal as compared to afternoon strokes, and this high fatality is related to circadian clock-mediated morning rise in blood pressure, increased hematocrit and platelet aggregation, and hypercoagulability.
**Objectives:** Description of diurnal and nocturnal oscillations in the mortality of ICU patients hospitalized with BCVA, analysis of the peak hours of mortality, as well as highlighting the most critical intervals in order to ensure targeted therapy in order to prevent mortality.
**Methods:** This is a retrospective study carried out between 01.10.2023–30.03.2024 in the ICU, IMSP SCM "Sf.Treime". The total number of patients hospitalized with BCVA was analyzed, in particular the number of deceased patients and the peak hours of deaths were investigated. The total number of patients hospitalized in the ICU was 409 and the number of those who died in the ICU was 142 (34.71%), the average age being 64.04 ± 3.45 years, women 46.94% ($n = 192$), men 53.05% ($n = 217$).
**Results:** Mortality was found to follow a biphasic circadian pattern. The following peak hours of mortality were highlighted: 02:00–04:00 (22.53% ($n = 32$)); 06:00–08:00 (11.26% ($n = 16$)); 11:00–12:00 (15.49% ($n = 22$)); 14:00–17:00 (28.87% ($n = 41$)); 23:00–00:00 (10.56% ($n = 15$)). In deaths with an average age of 54.40 years ± 2.42 years, peaks were observed at 09:00–10:00 (4.92% ($n = 7$)) and 17:00–19:00 (6.33% ($n = 9$)). At the same time, time intervals were highlighted where no deaths were recorded, these being 00:00–01:00 and 13:00–14:00 which also outline a day–night rhythmicity.
**Conclusions:** This study documented the circadian pattern of mortality in patients with acute cerebrovascular diseases admitted to the ICU. In addition, the importance of appropriate therapy at certain hours of the day and night was noted. These evidences opening new perspectives in chronotherapy and chronoprophylaxis of acute cerebrovascular diseases. The precise role of circadian clocks in stroke and related cerebrovascular diseases needs to be addressed in future studies. In addition, investigating the molecular mechanisms that underlie the association between circadian rhythms and stroke would be an important step toward developing specific therapeutic strategies.

**Introduction:** Assessing pulmonary aeration in mechanically ventilated patients is crucial for optimizing ventilation and preventing complications [1]. Acute respiratory distress syndrome (ARDS) exacerbates lung function impairment, leading to shunt, dead space and altered lung mechanics [2]. The lung ultrasound score (LUS) and the Radiographic Assessment of Lung Edema (RALE) score are increasingly used to semiquantify pulmonary aeration and edema [3,4]. We aimed to examine the association between LUS and RALE scores, and metrics of shunt, dead space, and respiratory mechanics in invasively ventilated patients.
**Methods:** Secondary analysis of the 'Diagnosis of Acute Respiratory Distress Syndrome' (DARTS) prospective observational study including ICU patients expected to be invasively ventilated for at least 24 h [5]. The global LUS aeration score (range 0 to 36) and the Radiographic Assessment of Lung Edema (RALE) score (range 0 to 48) were used as scores of lung edema. Physiological metrics included the PaO2/FiO2 ratio as a surrogate of shunt, ventilatory ratio and corrected minute volume for dead space, and dynamic respiratory system compliance, driving pressure, and mechanical power as respiratory mechanics variables. The analysis was performed for all patients combined and repeated in the ARDS subgroup. Associations were tested through linear regression and the coefficient of determination (R2) was reported.
**Results:** This analysis comprised 364 DARTS patients, of which one-third suffered from ARDS, with 32% ICU-mortality. Median RALE and global LUS scores were 15 [8 to 20] and 7 [3 to 13], respectively. Both RALE and global LUS scores exhibited modest inverse associations with PaO2/FiO2, albeit the global LUS score had a stronger association as compared to RALE (R2 = 0.12 vs. R2 = 0.05, respectively). Both scores explained very little variance of ventilatory ratio, corrected minute volume, respiratory system compliance and driving pressure (R2 < 0.1 for all associations). The RALE score had a stronger association with mechanical power as compared to the global LUS score (R2 = 0.12 vs. R2 = 0.05, respectively; Figure). Limiting the analysis to the ARDS subgroup did not improve the associations.
**Conclusions:** Our study reveals a weak association between the RALE, the global LUS score and metrics of shunt, dead space, and respiratory metrics in invasively ventilated patients, emphasizing the necessity of a comprehensive lung assessment, combining radiographic and physiological measures.

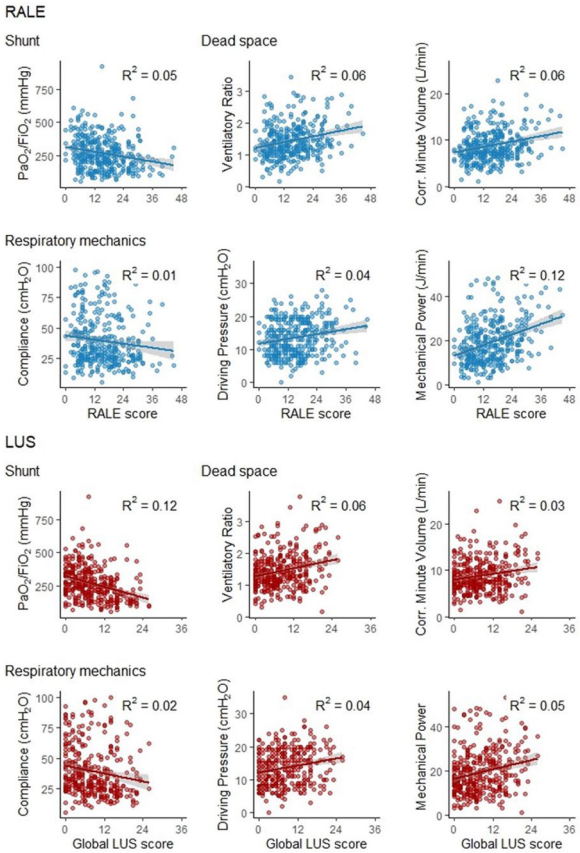

**Fig. (abstract 001384)** Association between the RALE score and global LUS score with metrics of shunt, dead space and respiratory mechanics. Scatterplots with dots independently representing the value of the imaging modality (RALE = blue; LUS = red) and their corresponding values of different measurements. The line represents linear regression with the 95% confidence interval plotted around it in grey

**Introduction:** Capillary leak index (CLI) has shown to be effective in prediction of mortality for patients with sepsis and septic shock. Cordemans et al. (2012) set a cutoff point for 61 in no survivors with CLI, also an accumulative fluid balance greater than 2000 ml at discharge traducing capillary leak. Palacios et al. (2018) published a cutoff point for CLI and mortality at 85 with a sensitivity 89% and specificity 100% in Kaplan–Meier curve for mortality at 28 days.
**Objectives:** To evaluate capillary leak index and fluid balance to mortality in septic patients.
**Methods:** This is a prospective cohort of adult patients during January to December 2023 in the High Specialty Regional Hospital in northeast Mexico, which included adult patients with sepsis and septic shock at admission. Continuous variables are described as means and standard deviation and categorical variables as percentages; t student test and Chi square were used accordingly to evaluate differences and p value < 0.05 was considered statistically significant.
**Results:** A total of 50 patients were included in this observational study. Two groups were formed respective to the capillary leak index (< 67/ > 67), and tested for mean differences. < 67 CLI group had a mean age 44.8 years (± 18.7) vs > 67 CLI group 60.9 (± 12.7, $p = 0.001$), males 14.9% vs 23.4% ($p = 0.94$), BMI (kg(m2) 27.5 (± 4.9) vs 30.4 (± 9.2, $p = 0.23$), comorbidities, hypertension 4.3% vs 34% ($p = 0.003$), T2 diabetes mellitus 17% vs 29.8% ($p = 0.79$); vasopressor use 31.9% vs 59.6% ($p = 0.11$), serum creatinine 2.7 (± 2.9) vs 2.2 (± 2.1, $p = 0.54$), albumin 3 (± 0.7) vs 2.4 (± 0.5), C-reactive protein (mg/dl) 95.6 (± 55.5) vs 300 (± 101, $p = 0.0005$), final fluid balance at ICU discharge mean was 3918.9 mL (± 5695) vs 2191 mL (± 5731, $p = 0.31$)), mechanical ventilation use 25.% vs 38.3% ($p = 0.75$), SOFA 8 (± 4) vs 8 (± 3, $p = 0.54$), SAPS 49 (± 20) vs 50 (± 19.3, $p = 0.88$), duration of mechanical ventilation was mean 7 days (± 8.8) vs 5.4 (± 5, $p = 0.42$), renal replacement therapy 14.9% vs 12.8% ($p = 0.17$), and discharge to home 14.9% vs 38.3% ($p = 0.12$).
**Conclusions:** Our population of older adults was associated with greater capillary leak, as well as those with chronic arterial hypertension. Despite T2DM being a chronic inflammatory state, these patients do not present with greater capillary leak. Likewise, the tendency to maintain fluid restriction is noted in those patients with greater capillary leakage. When using the capillary leak index with a cutoff value of 67, there is no difference between mortality, days of mechanical ventilation or renal replacement therapy. However, just as Meyhoff (2022) demonstrated that restrictive or liberal fluid intake does not impact mortality, and therefore, there is no benefit in using large volumes of fluids. It will be necessary to use another cutoff point or inflammatory marker for greater prediction of mortality in patients with sepsis and septic shock.

**Introduction:** Severe invasive infections caused by streptococcus subspecies, especially Group A (*S. pyogenes*) and *S. pneumoniae*, have emerged as an increasing cause of death and morbidity in the intensive care unit (ICU) over the past years. The release of exotoxins and superantigens into the bloodstream and subsequent cytokine release are considered as the main drivers of consecutive septic shock. Therapeutic plasma exchange (TPE) in early septic shock has demonstrated improved clinical outcomes, but its therapeutic significance in streptococcal disease in particular remains unclear.
**Objectives:** To investigate effects of TPE on major clinical outcomes in patients with streptococcus related septic shock.
**Methods:** We conducted a retrospective, multicenter observational cohort study, including adult patients with streptococcal infection-related septic shock between 2012 and 2024 at three tertiary university hospitals in Germany and Switzerland. Primary outcome was 90-day ICU mortality, key secondary outcomes included vasopressor-inotropic score (VIS) reduction at 24 h and other markers of organ dysfunction.
**Results:** These preliminary results only include one of three centers. Between 2012 and 2024, 70 patients were identified with streptococcus related septic shock. 25 patients underwent TPE, while 45 patients received standard of care (SOC). Main identified streptococcus subspecies were 30% *S. pyogenes*, 40% *S. pneumonia*, 30% other *S.* spp. At admission, patients in the TPE group exhibited considerably higher markers of organ dysfunction: SOFA-Score: 13 vs 9 points, lactate: 6.9 vs 4.3 mmol/l, VIS-Score 83 vs 60 and renal replacement therapy in 100% vs 49%, (all $p < 0.001$). In the Cox-regression model for 90-day ICU mortality, SOFA-score adjusted HR with TPE was 0.39 ($p = 0.049$) (Figure A). In the TPE group, there was a significant reduction in the VIS after 24 h compared to SOC (−35% [IQR −51; 5] vs 0% [IQR −18; 6], $p = 0.011$) (Figure B). Also, vasopressor-free days were higher with TPE (10 [IQR 0;34] vs 2 [IQR 0;6], $p = 0.02$). Within the TPE group, increasing VIS after 24 h was highly associated with ICU mortality (univariable HR: 6.04, $p = 0.02$), but this did not apply to the SOC group (Figure C).
**Conclusions:** In this preliminary analysis only including one of three centers, TPE was associated with improved clinical outcomes in streptococcus-related septic shock despite higher degree of multi-organ dysfunction at admission. Reduction in vasopressor use after 24 h was predictive of survival within the TPE group, but not the SOC group. Complete analysis of remaining centres is pending.

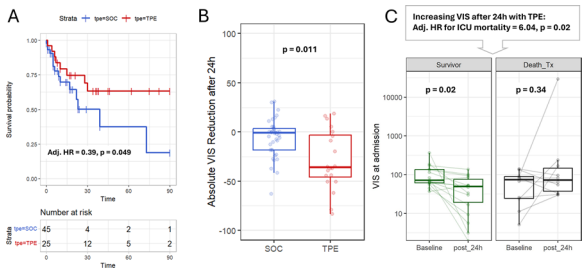

**Fig. (abstract 001387)** A) Kaplan–Meier plot showing 90-day ICU survival between TPE and SOC. B) Absolute VIS reduction after 24 h. C) Association between delta VIS and survival in the TPE group

**Introduction:** Arterial hypotension has been associated with complications such as renal failure and increased mortality. The hypotension prediction index (HPI) allows the prediction of hypotension based on the analysis of the arterial blood pressure waveform (1). It has been validated for intraoperative hypotension; however, studies in critically ill patients are scarce.
**Objectives:** To evaluate the performance of HPI as a predictor of arterial hypotension in postoperative cardiac surgery patients.
**Methods:** This single-center, prospective, observational study was approved by the ethics committee. Patients aged ≥ 18 years who signed the informed consent form and were admitted to the ICU after programmed cardiac surgery were included. An arterial pressure catheter inserted into the radial artery was connected to an Acumen IQ sensor (Edwards Lifesciences, Irvine California, USA) and to a HemoSphere monitoring platform (Edwards Lifesciences, Irvine California, USA) to obtain the mean arterial pressure (MAP) and HPI (which was blinded on the monitor) every 20 s.
The first 12 h of the postoperative period was analyzed. Hypotension was defined as any period with a MAP < 65 mmHg for at least 1 min. Hypotension events separated by at least 15 min were used to evaluate HPI performance. HPI values were recorded 5, 10, and 15 min before the start of hypotension. A non-hypotensive event was defined as a 30 min continuous section data points with a MAP ≥ 75 mmHg and at least 20 min apart from any hypotensive event. The difference between MAP at 20 s (dMAP20s), 1 min (dMAP1min), and 3 min (dMAP3min) was used to compare the prediction ability.
The area under the ROC curve (AUROC) was calculated for each parameter. The optimal cutoff point was obtained as the point closest to the (0,1) point in the ROC curve. The area of MAP < 65 mmHg normalized by the observation time (TWA65mmHg) was calculated.
**Results:** 41 patients were included, with an age of 68 [62–72] years and 58% were male. Thirty-four percent underwent valvular surgery, and 51% of the patients underwent coronary by-pass. EUROSCORE II was 1.9 [0.74–3.86]. One patient died before starting data acquisition and 3 required re-intervention. For the latter, the time before and 12 h after re-intervention was analyzed. Total observation time was 29,641.33 min. Total hypotension time was 2401.67 min (8%). A total of 362 hypotensive events were recorded. 32 patients experienced at least one hypotensive event. The duration of the events was 2.33 [1.33–6] mins. TWA was 0.1 [0.01–0.4] mmHg. 96 episodes were used for the AUROC analysis. HPI AUROC was above 0.91, with a sensitivity and specificity above 80 and 88%, respectively, for the best cutoff point for the three evaluated periods (Table 1). AUROC for dMAP was approximately 0.5.
**Conclusions:** HPI predicted arterial hypotension during the first 12 h after programmed cardiac surgery and may help to act early to prevent hypotension and reduce potential complications.

**Table 1 (abstract 001390)** Area under ROC curve (AUROC), optimal cutoff, sensitivity, specificity for the evaluated parameters (HPI and MAP difference at 20 s, 1 min, 3 min and 5 min) to predict hypotension 5, 10 and 15 min before its onset.

| Variable | Time to event (min) | AUROC | Best cut-off point | Sensitivity (%) | Specificity (%) |
|---|---|---|---|---|---|
| HPI | 5 | 0,913 | 49 | 80,21 | 92,44 |
| | 10 | 0,923 | 44 | 79,57 | 88,37 |

***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001391

**Introduction:** Legionnaires' disease is a form of severe pneumonia caused by a Gram-negative aerobic intracellular bacteria. Between October 1st and November 30th 2023, Portugal registered a sudden increase of notified Legionnaires' disease cases throughout the country. A cluster was identified on the northern coast region with multiple cases, most requiring hospitalization at the peripheral hospital of the region. We took this epidemiological situation as an opportunity to review and analyze all Legionnaires' disease patients with severe disease admitted to the Hospital de Santa Luzia Intensive Medicine Department—intensive (ICU) or intermediate (IMCU) care units—in the last 3 years.
**Objectives:** To report the epidemiology, clinical features, treatment strategies and outcomes of patients admitted with Legionnaires' disease to the Intensive Medicine Department.
**Methods:** Data of patients with microbiologically documented Legionnaires' disease admitted to the ICU or IMCU was retrospectively collected between January 1st 2020 and December 31st 2023.
**Results:** In total, 10 patients with Legionnaires' disease were admitted with severe disease to the department. Of the 2023 cluster (17 patients with a positive test at our hospital), 4 (23.5%) were admitted to the IMCU and 3 (17.6%) to the ICU—41.2% admission rate. The remaining cases occurred in 2020 ($n=1$, 10%) and 2021 ($n=2$, 20%). Patients' mean age was 63 years old (Standard Deviation (SD) 19.4) and 80% ($n=8$) were males. Mean APACHE II, SAPS II and admission SOFA scores were 10.7 (SD 2.31), 32.2 (SD 11.58) and 5.1 (SD 2.42), respectively. Diagnose was made in all cases with a positive urinary antigen and in two cases with a positive PCR analysis too. Radiological lung changes at admission were noticed in all patients. Length of stay at the ICU was on average 11 days (SD 5.0) and at the IMCU 6.9 days (SD 6.26). At least one classic risk factor for Legionnaires' disease (such as smoking, pulmonary structural disease, diabetes disease or immunosuppression) was presented by 60% ($n=6$) of patients. The main cause of admission was respiratory failure ($n=9$, 90%) but 60% ($n=6$) of patients also presented multi-organ failure and 50% ($n=5$) presented acute kidney injury. No patient evolved to septic shock. Invasive mechanical ventilation was necessary in 2 cases (20%, mean duration 11 days, SD 4.3) and non-invasive ventilation or high-flow nasal cannula was used in 7 (70%) patients. Regarding antibiotic choice, azithromycin was used in 60% ($n=6$) of patients. A PCR decrease by half or more was noted 48 h after antibiotic treatment initiation in 7 (70%) patients. Survival rate was 100% ($n=10$).
**Conclusions:** Legionnaires' disease is an uncommon cause of admission to our ICU and IMCU with only 10 cases registered for 3 years. A cluster of Legionnaires' disease was identified in our region of Portugal in November 2023 with a 41.2% admission rate to the Intensive Medicine Department.

**Correspondence:** V.M. González Manzano
***Intensive Care Medicine Experimental*** 2024, **12(suppl 1):**001392

**Introduction:** Septic shock is a severe complication of sepsis with high mortality, characterized by circulatory and metabolic instability. Although various hemodynamic parameters have been used for its management, cardiac power (CP) has emerged as a potential predictor of clinical outcomes.
**Objectives:** To assess the utility of cardiac power as a predictor of mortality in patients with septic shock in an Intensive Care Unit (ICU).
**Methods:** A prospective, observational, longitudinal study was conducted at the ABC Medical Center from March 2023 to January 2024. Adults over 18 years of age diagnosed with septic shock were included, excluding those with cardiogenic shock or acute myocardial infarction at admission. CP was measured using non-invasive techniques, and its association with mortality and ICU stay duration was analyzed.
**Results:** The study included 23 patients, of which 40% had a CP lower than 0.6 W. A significant correlation was found between low CP and higher mortality ($p<0.05$). In addition, patients with a low CP had a longer ICU stay compared to those with a higher CP.
**Conclusions:** Cardiac power is an effective indicator for predicting mortality and could be useful for guiding therapeutic interventions in patients with septic shock. These findings suggest that CP monitoring could be incorporated as part of the standard management in the ICU for patients with this condition.

**Introduction:** Blunt chest trauma (BCT) stands as a significant cause of trauma admissions globally, often requiring mechanical ventilation and exhibiting notable morbidity and mortality rates.
**Objectives:** To report BCT data within a non-trauma center and analyze variable associations with mortality.
**Methods:** A single-center retrospective cohort study of all adult patients admitted with BCT to the intensive or intermediate care unit of a non-trauma center was conducted between October 1st 2020 and October 31st 2023. Statistical analysis was done using Chi square and Mann–Whitney U tests.
**Results:** In total, 99 patients were admitted for BCT with 77.8% ($n=77$) being male and 22.2% ($n=22$) female, averaging 64.22 (SD = 17.5) years of age. Median duration of stay was 4 (IQR 5) days. Isolated chest trauma occurred in 31.3% ($n=31$) of cases. Severity scores at admission were SAPS II (Mdn = 24, IQR = 19), APACHE II (Mdn = 10, IQR = 6), SOFA (Mdn = 3; IQR = 3) and Injury Severity Score (ISS) (Mdn = 13, IQR = 13). Complications included lung contusion ($n=37$, 37.4%), pneumothorax ($n=34$, 34.3%), hemothorax ($n=42$, 42.4%) and flail chest ($n=15$, 15.2%). Non-invasive ventilation (NIV) was used in 33.3% ($n=33$) of patients and invasive ventilation in 12.1% ($n=12$). Notably, 26.7% ($n=4$) of flail chest patients and 23.5% ($n=8$) with pneumothorax only required NIV. Pain management with regional anesthesia was performed in 34.3% ($n=34$) of cases, with 17.7% ($n=6$) still requiring a strong systemic opioid. Patients with no regional anesthesia received opioids in 33.9% ($n=22$) of cases. Hospital-acquired infections rate was 41.4% ($n=41$), predominantly respiratory infection (80.5%, $n=33$). In-hospital mortality rate was 10.1% ($n=10$).
Chi-square test of independence showed significant association between mortality and need for NIV ($\chi2(1)=6.73$, $p=0.009$), invasive ventilation ($\chi2(1)=14.77$, $p<0.001$), use of strong systemic opioids ($\chi2(1)=5.52$, $p=0.019$) and hospital-acquired infection ($\chi2(1)=6.83$, $p=0.009$). No statistically significant association between mortality and sex ($\chi2(1)=0.39$, $p=0.544$), presence of flail chest ($\chi2(1)=0.23$, $p=0.634$), pulmonary contusion ($\chi2(1)=0.26$, $p=0.009$), hemothorax ($\chi2(1)=0.70$, $p=0.404$), pneumothorax ($\chi2(1)=1.02$, $p=0.316$), need for chest tube ($\chi2(1)=0.297$, $p=0.588$) and use of regional anesthesia ($\chi2(1)=2.923$, $p=0.089$) was found.
Mann–Whitney test showed that patients with greater SOFA ($Z=-3.81$, $p<0.001$), APACHE II ($Z=-2.79$, $p=0.005$) and SAPS II ($Z=-3.88$, $p<0.001$) scores had significantly greater mortality. No significant difference in mortality between age groups ($Z=-1.17$, $p=0.241$), duration of stay ($Z=-0.51$, $p<0.61$), number of fractured ribs ($Z=-0.99$, $p=0.32$) and ISS score ($Z=-0.391$, $p=0.695$) was found.
**Conclusions:** We report a relatively low use rate of NIV and invasive ventilation. In-hospital mortality was on the lower spectrum of the literature reported rate. Strong systemic opioid use, need for mechanical ventilation and nosocomial infection were associated with mortality.

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001394

**Introduction:** Acute Kidney Injury (AKI) refers to the sudden loss of renal function determined by an increase in serum creatinine levels and/or a reduction in urine volume, limited to a duration of 7 days. The main factors for the development of AKI in intensive care units are sepsis, hypovolemia, cardiovascular diseases, age > 60 years, diabetes mellitus, and arterial hypertension. The presence of renal pathology represents an increased burden of morbidity and mortality, increased costs due to longer hospital stays, and especially in cases where it leads to Chronic Kidney Disease. There is limited information in Mexico and generally in Latin America; however, the importance of early detection is undeniable.
**Objectives:** To identify risk factors associated with acute kidney injury in patients admitted to the intensive care unit.
**Methods:** Case–control studies in patients admitted to intensive care without acute kidney injury were conducted. Two groups were integrated: patients with acute kidney injury (cases) and patients without acute kidney injury (controls) within 24 h of admission to the service. The diagnosis of AKI was established with an increase in baseline creatinine greater than 0.3 mg/dL. The sample size was 30 cases and 38 controls. Statistical analysis included averages, percentages, *t*-test for independent groups, chi-square test, odds ratio, confidence

interval for odds ratio, ROC curve, sensitivity, specificity, multiple logistic regression model, and calculation of the probability of the event occurrence.
**Results:** The logistic regression model showed that when the Sequential Organ Failure Assessment (SOFA) score at admission is greater than 3.5 and the admission creatinine is greater than 0.85, the probability of presenting acute kidney injury at 24 h is 60.1%. If the baseline SOFA score is less than 3.5 and the baseline creatinine is less than 0.85, the probability of presenting acute kidney injury at 24 h is 16.5%. There were no significant differences in the rest of the variables (sex, age, comorbidities, vasopressor therapy, invasive mechanical ventilation, or urine output/hour at admission).
**Conclusions:** There are various factors that may predispose critically ill patients to AKI such as coronary artery disease, chronic liver disease, use of nephrotoxic drugs, sepsis, vasopressor therapy, etc. In our study, consistent with other studies, the variables of statistical significance were SOFA score and baseline creatinine, mentioning a cutoff point of 3.5 and 0.85 mg/dL respectively, which together, give a risk of more than 50% for the development of AKI, thus helping to recognize and implement interventions to reduce morbidity and mortality.

**Table 1 (abstract 001394)** Comparison of sex, age, and comorbidities in patients with and without acute kidney injury 24 h after admission to the intensive care unit.

| Age (years) | Acute Kidney Injury (n=30) | No Acute Kidney Injury (n=38) | T test | p |

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001395

**Introduction:** The widespread use of antiretroviral therapy in the treatment of HIV-infected patients leads to a significant reduction in their morbidity and mortality, although ICU admission remains frequent.
**Objectives:** We aim to characterize the epidemiology and outcomes of HIV-infected patients admitted to the ICU, during and after the COVID-19 pandemic, to explore its possible impact on the follow-up and treatment of these patients.
**Methods:** A single-center, retrospective, observational study of critically ill HIV-infected patients was performed between 1st March 2020 and 1st March 2024. Patients were divided into COVID or post-COVID era, according to their admission in the first or second 24 months of the study period, when the follow-up of the majority of outpatients was performed virtually or presentially by default, respectively. Statistical analysis was performed by IBM SPSS Statistics v. 29.
**Results:** A total of 3282 patients were admitted to the UCI during the study period. Among these, 69 patients were HIV-infected, with a median age of 56 years, 638% were male and 667% caucasian. HIV infection was newly diagnosed in 174% of the patients. The majority of admissions were for non-AIDS-defining conditions (884%). Respiratory illness (348%), sepsis and septic shock (275%), and neurological disorders (145%) were the main conditions that lead HIV-infected patients to the ICU. During ICU stay, 638% of the patients needed vasopressors and/or inotropes, 652% mechanical ventilation and 246% renal replacement therapy. Comparing patients admitted during the COVID ($n=30$) and post-COVID era ($n=39$), median APACHE II was 19 vs 18, median SAPS II 53 vs 42, AIDS-defining infection at ICU admission was 26.7% vs 30.8%, CD4 level 461 vs 435 cells/uL, viral load 162 vs 90 RNA copies/ml, respectively (all $p$-values > 0.05). ICU mortality in the post-COVID era was higher than in the COVID era (308 vs 16.7%) but did not reach statistical significance.
**Conclusions:** Respiratory illness remains the main indication for ICU admission in HIV-positive patients. ICU mortality of HIV patients remain high but did not change between COVID and post-COVID era.

## Modified renal angina as a predictor of acute kidney injury in critically ill patients in the intensive care unit

E. Rocha[1], N. Queb[1], C.J. Gaytán García[2], R. Carbajal Serrano[3], B. Martinez[4], J.S. Aguirre Sanchez[4]
[1]Intensive Care Unit, ABC Observatory Medical Center, Ciudad de México, Mexico, [2]Critical Medicine, ABC Observatory Medical Center, Ciudad de México, Mexico, [3]Intensive Care Unit, The American British Cowdray Medical Center, MEXICO, Mexico, [4]Critical Care Unit, ABC Medical Center, Ciudad de México, Mexico
**Correspondence:** E. Rocha
***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001396

**Introduction:** Acute kidney injury (AKI) is defined by a sudden loss of excretory renal function, its management in critical care settings is challenging, with a poor prognosis. The Renal Angina Index (RAI) is a tool that incorporates clinical parameters within the first day of admission, grouped into two categories: risk and injury. It has been validated in the pediatric population to aid in the risk stratification of AKI within 3 days of admission to the intensive care unit, with notably higher performance than single changes in serum creatinine for the incidence of acute kidney injury. In a subanalysis of clinical studies, modifications were made to the risk category for its applicability. The diagnostic performance of this index in the adult population has not been as accurate.
**Objectives:** To demonstrate that the modified renal angina index is useful for predicting the occurrence of AKI in critically ill patients.
**Methods:** Retrospective, observational, longitudinal, and single-center study. It was conducted on patients admitted to the intensive care unit without acute kidney injury, with at least 24 h of stay, baseline creatinine was taken and 24 h later, patients with AKI, chronic kidney disease, treatment with renal replacement therapy, and gestational status were excluded. Modified Renal Angina Index (mRAI) was calculated, AKI was established with an increase in baseline creatinine greater than 0.3 mg/dL for stage 1 defined by the Kidney Disease: Improving Global Outcomes (KDIGO) creatinine criteria. Statistical analysis included an ROC curve to determine the highest sensitivity and specificity, chi-square test, and odds ratio.
**Results:** RAIm showed good performance with the occurrence of AKI with an AUC of 0.88 (95% CI: 0.80 to 0.97). In the group with mRAI greater than 7, the prevalence of acute kidney injury was 75.5%, and in the group with mRAI of 7 or less, the prevalence of acute kidney injury was 15.4% ($p = 0.001$). For every 17 patients with a renal angina index greater than 7 who have acute kidney injury, there is 1 patient with a renal angina index of 7 or less who also has acute kidney injury.
**Conclusions:** In our study, we found that the RAIm greater than 7, as reported in the literature, is a predictor of AKI, from stage 1, being a useful, simple, applicable and economical index, allowing us to anticipate fatal outcomes and complications in the intensive care unit.

**Introduction:** Observational evidence supports the correlations between immune traits and acute respiratory distress syndrome (ARDS) [1–3]. A recent mendelian randomization (MR) Study found the causal relationship between two immune cell subtypes and ARDS [4]. However, causal associations of numerous immune traits with ARDS remained unknown. Furthermore, metabolic reprogramming of immune cells was found to be correlated with dysregulated inflammation response [5], indicating that serum metabolites may mediate between immune traits and ARDS. In this study, we applied two-step MR analyses to examine causality and mediators between 731 immune traits and ARDS risk.
**Methods:** A total of 731 immune traits, including 118 absolute cell counts, 192 relative counts, 389 median fluorescence intensity (MFI) of surface antigens and 32 morphological parameters, were recruited. This study utilized genome-wide association studies (GWAS) on 731 immune traits as exposure and an ARDS GWAS from the Finngen database as the outcome [6]. GWAS on 1400 serum metabolites were also used as a potential mediator [7]. In this study, a two-step Mendelian randomization method is used to calculate the mediation effect. The inverse variance weighted (IVW), MR-Egger and weighted median were performed for comprehensive assessment of the causality. Sensitivity analyses were conducted with Cochrane's Q test, MR-Egger intercept, MR-PRESSO and leave-one-out analysis. In addition, replication MR and Steiger test were also implemented to verify the causation.
**Results:** Our study identified that 10 genetically determined immune traits were causally associated with ARDS risk. High expression of CD8 on Effector Memory CD8+T cell (OR=1.58, 95% CI: 1.13–2.21, $p=0.008$), CD25 on IgD+CD38- naive B cell (OR=1.75, 95% CI: 1.14–2.68, $p=0.011$), and CD25 on IgD+CD38+B cell (OR=1.85, 95% CI: 1.14–3.02, $p=0.013$) were most significantly associated with a higher risk of ARDS. CD20 on IgD+CD24− B cell (OR=0.60, 95% CI: 0.40–0.92, $p=0.020$), CD20 on naive-mature B cell (OR=0.62, 95% CI: 0.41–0.93, $p=0.022$), CD20 on B cell (OR=0.61, 95% CI: 0.40–0.93, $p=0.023$), CD20 on IgD+B cell (OR=0.65, 95% CI: 0.44–0.96, $p=0.029$), CD25 on IgD+CD24− B cell (OR=1.62, 95% CI: 1.05–2.51, $p=0.031$), CD45RA+CD28− CD8+T cell %T cell (OR=1.00, 95% CI: 1.00–1.00, $p=0.033$), and CD20 on IgD+CD38dim B cell (OR=0.71 95% CI: 0.52–0.98, $p=0.037$) also had potential casual relationship with ARDS. Mediation analysis revealed that the Hypotaurine to cysteine ratio mediated the causal relationship between CD8 on Effector Memory CD8+T cell and ARDS, and the proportion of mediating effect was 38.8%. 5-hydroxylysine levels mediated the causal relationship between CD25 on IgD+CD24− B cell and ARDS, and the proportion of mediating effect was 11.8%.
**Conclusions:** This research unveils the intricate network between immune traits and ARDS, thus providing novel perspectives into the development mechanism of ARDS and potential therapeutic targets for further research.

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001400

**Introduction:** In situ simulation (ISS) is a key training strategy in critical care settings. This study aimed to evaluate the impact of an ISS program on critical care staff's self-perception of their skills and their satisfaction with the training received.
**Methods:** A quantitative post-intervention study was conducted to assess the self-perception and satisfaction of critical care unit staff following the implementation of an ISS program. Data were collected using self-administered questionnaires, including the SET-M and Likert scales.
**Results:** The study included 61 participants with a median age of 32 years, a male-to-female ratio of 1:2, and a median experience of 8 years (IQR 5–12.25). During the first semester, each respondent participated in an average of 1.7 simulations, and 77% had prior simulation experience. Overall satisfaction with the program was high, with a global evaluation of 9.45/10. The impact on self-perception, assessed using applicable items from the SET-M scale, showed an average of 2.7/3 across dimensions, indicating strong agreement with the favorable impact of ISS.
**Conclusions:** ISS is not only feasible but also highly valued by critical care staff. The program's impact on staff's self-perception and satisfaction reflects a very positive overall evaluation, suggesting that ISS is associated with perceived improvements in performance. These findings add a new dimension to the analysis of ISS in critical care settings, highlighting its potential benefits for staff development and confidence.

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001401

**Introduction:** Healthcare professionals working with critically ill patients face various emotional stressors that can impact their well-being and patient care. In situ simulation (ISS) is a training tool that can potentially strengthen emotional management skills. This study aimed to interpret the emotions of healthcare professionals working in critical care services and participating in ISS scenarios to develop strategies for enhancing their emotional management.
**Methods:** A qualitative descriptive phenomenological study was conducted. Data were collected through semi-structured interviews with healthcare professionals working in critical care units who had participated in ISS during the past two years. Interviews were recorded and analyzed using Colaizzi's method.
**Results:** Two main themes emerged from the data: emotions in the intensive care unit (ICU) and emotions in clinical simulation. Within the ICU theme, participants reported experiencing both negative emotions (fear, sadness, guilt, nervousness, and anxiety) and positive emotions (gratification, tranquility, and adrenaline rush). Empathy and emotional fatigue were identified as recurring concepts. Participants also discussed strategies for managing emotions and crisis situations. Within the clinical simulation theme, participants expressed negative emotions (uncertainty, anger, and nervousness) and positive emotions (tranquility and confidence). They recognized the benefits of simulation, such as increased professional security, error identification, team training, and improved organization.
**Conclusions:** Emotions play a crucial role in the professional performance of healthcare workers caring for critically ill patients. ISS can be an effective tool for strengthening emotional management skills. Incorporating strategies to address the emotional well-being of healthcare professionals, such as debriefing sessions focused on emotions and simulations targeting soft skills like effective communication, can potentially enhance their emotional resilience and patient care.

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001403

**Introduction:** Sepsis and septic shock are life-threatening conditions associated with significant morbidity and mortality. Recent studies have suggested a potential link between cholesterol levels and outcomes in septic patients. This study aimed to investigate the association between admission cholesterol levels and mortality in patients with sepsis and septic shock.
**Methods:** A retrospective cohort study was conducted on patients with sepsis and septic shock admitted to Son Llatzer Hospital in Palma, Mallorca, Spain, between 2006 and 2022. The Sepsis-2 definition was primarily used for patient classification. Differences in mean cholesterol values among sepsis, severe sepsis, and septic shock groups were analyzed using ANOVA. Logistic binomial regression was performed to assess the relationship between admission cholesterol levels and mortality.
**Results:** 5780 Admission cholesterol samples from septic patients were analyzed. Levels were significantly lower in patients with septic shock compared to those with sepsis and severe sepsis ($110.489 \pm 2.306$ mg/dL vs. $128.804 \pm 3.270$ mg/dL and $124.795 \pm 1.200$ mg/dL, respectively; $p < 0.001$). Logistic regression analysis revealed a significant association between lower admission total cholesterol levels and increased mortality (odds ratio: 0.990; 95% CI: 0.988–0.993; $p < 0.0001$).
**Conclusions:** In this retrospective cohort study, lower admission cholesterol levels were significantly associated with septic shock and increased mortality in patients with sepsis and septic shock. These findings suggest that admission cholesterol levels may serve as an additional, and usually available, prognostic marker to be considered in septic patients. Further research is needed to elucidate the underlying mechanisms and potential therapeutic implications of this association.

**Correspondence:** M. Rovegno
***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001404

**Introduction:** Today, intensive care medicine has expanded to the undergraduate curriculum, providing a true opportunity for medical students to be involved in the care of critical scenarios and to understand from a practical point of view complex physiological concepts [1]. Our department provides undergraduate teaching on the fundamentals of organ failure, including acute respiratory failure (ARF). COVID-19 pandemic forced us to shift to a simulation-based scenario of ARF in the context of remote classes. We used a mechanical ventilator software simulator for this experience. Since 2022, we returned to in vivo training, including real-life demonstrations of ARF in ICU. We decided to maintain both experiences, simulation-based cases, and real-life exposure. Moreover, there is paucity of evidence on which educational strategy should be first introduced, either simulation or clinical scenario, to enhance user satisfaction and learning outcomes.

**Objectives:** Our main aim was to evaluate the educational impact of exposure sequence (simulation first vs clinical first) on students' learning outcomes and satisfaction.
**Methods:** We performed a randomized crossed-over educational controlled study. Briefly, all medical students admitted for the human physiology regular course of the 2022 cohort were randomly assigned to the sequence simulation—ICU visit (Group 1) or ICU visit—simulation (Group 2). In both scenarios, we reviewed concepts of normal respiratory physiology and ARF measuring and interpreting FiO2, pO2, pCO2, PaO2:FiO2, Vd/Vt, A-aO2 gradient, plateau pressure, PEEP, driving pressure, lung compliance, air resistance and identifying the main hypoxemia mechanism. The students tabulated their measures and interpretation using an electronic survey (google form). Both forms (simulation and ICU visit) were identical. We evaluate the adequacy of responses, the time spent to fill the form, and satisfaction (5-point scale). Data was analyzed using unpaired T Student test and are presented as mean DS.
**Results:** During November 2022, we randomized 114 undergraduate medical students to both exposure sequences. Male 60%, 20 years old. Group 2 (ICU first) obtained a discrete but significantly better performance with a 23.65 score (31 maximal) vs 21.56 score Group 1 (Simulator first) $p = 0.047$ (Fig. 1A). In addition, Group 2 required less time to complete their form (84.5 vs 105 min, $p = 0.04$; Fig. 1B). Consistent with these results Group 2 had a better satisfaction experience measured by a survey where they opined that methods, tests, information, and overall satisfaction were better using the sequence ICU first (Fig. 2A–D).
**Conclusions:** Undergraduate students had higher satisfaction and a better learning experience when they were initially assigned to ICU exposure rather than simulation first. Although these results rejected our hypothesis, we believe that simulation fatigue [2] and the opportunity to interact with both patients and healthcare teams impacted students' satisfaction and learning.

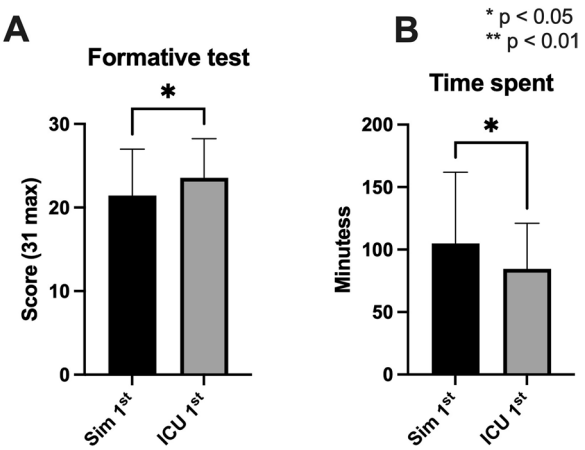

**Fig. 1 (abstract 001404)** Students randomly assigned to teaching at the ICU first obtained better grades and required less time to answer the tests than teaching based on a mechanical ventilator software simulator (Sim) first

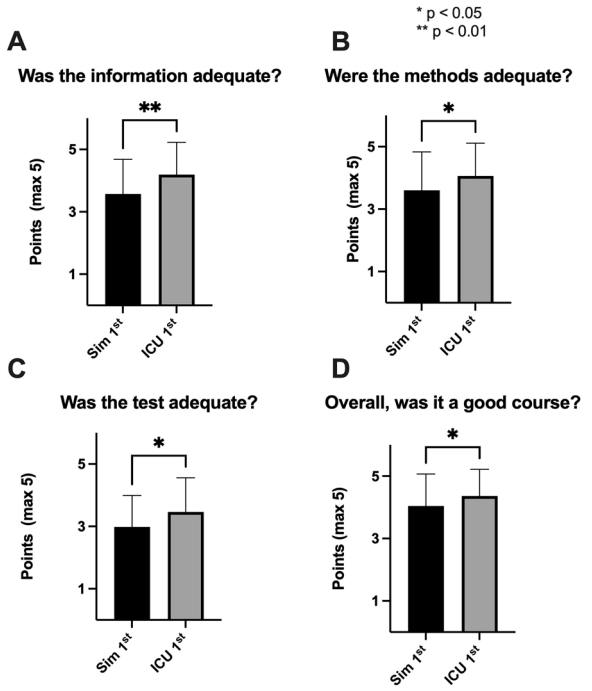

**Fig. 2 (abstract 001404)** Students randomly assigned to teaching at the ICU first experienced greater satisfaction than teaching based on a mechanical ventilator software simulator (Sim) first

## Using baseline pulse pressure variation predicts an achievement of negative fluid balance in 6 h after diuretic injection in septic shock patients

K. Chotchaisthit[1], S. Morakul[2], P. Theerawit[1], W. Mongkolpun[3]
[1]Critical Care, Faculty of Medicine Ramathibodi Hospital, Mahidol University, Bangkok, Thailand, [2]Anesthesiology, Ramathibodi Hospital, Mahidol University, Bangkok, Thailand, [3]Department of intensive care, Siriraj Piyamaharajkarun Hospital Faculty of Medicine Mahidol University, Bangkok, Thailand
**Correspondence:** W. Mongkolpun
***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001407

**Introduction:** Fluid resuscitation is a principal treatment in shock patients, however, it causes organ dysfunctions. To achieve a negative fluid balance (NFB), it aims to reduce organ edema, however, hypotension might occur resulting in tissue hypoperfusion and premature cessation of NFB.
**Objectives:** To evaluate whether baseline hemodynamic variables, pulse pressure variation (PPV), stroke volume variation (SVV) and change after the passive leg raising test (PLR) were related to an achievement of NFB without hypotension.
**Methods:** Recovery shock patients (MAP ≥ 65 mmHg without an increase of vasopressor or fluid bolus ≥ 6 h) who planned to undergo an achievement of NFB by diuretic were included. A PLR was performed before the diuretic injection. Hemodynamic variables were recorded before and immediately after PLR and changes in these variables during PLR were calculated as percentages. Cardiac output (CO) was obtained by pulse contour analysis. Positive fluid responsiveness (+veFR) was classified by ΔCO > 10% after PLR. All patients were divided by an achievement of NFB > 500 ml in 6 h after diuretic injection without hypotension (MAP < 65 mmHg or an increase in norepinephrine dose (NE)) (success vs unsuccess). Receiver operating characteristic (ROC) curves were performed and the area under the curves (AUCs) were calculated to predict whether the achievement of NFB would be successful.
**Results:** A total of 31 septic shock patients were included. The SOFA scores at inclusion time were 4 (2–5). All patients required NE at a dosage of 0.1 (0.1–0.3) mcg/kg/min. Fluid accumulation before inclusion was 2.3 (1.3–3.4) L. The time from shock diagnosis to inclusion time was 72 (48–120) hours. Of the 31 patients, 20 were in the success group and 11 patients of these were +FRve. There were no differences in baseline hemodynamic variables and changes after PLR between patients in the success and those in the unsuccess groups (Table 1). Baseline PPV and SVV were higher in patients in the success group than for those in the unsuccess group (Table 1). Baseline PPV had the highest AUC for predicting a successful NFB with cut-off values ≤ 7 (sensitivity 80%, specificity 81%) (Fig. 1).

**Table 1 (abstract 001407)** Baseline hemodynamic variable at inclusion in success and unsuccess group

| | All patients (*n* = 31) | Success group (*n* = 20) | Unsuccess group (*n* = 11) | *p*-values |
|---|---|---|---|---|
| SOFA | 4 (2–5) | 4 (1–5) | 5 (4–6) | 0.02 |
| MAP (mmHg) | 85 (77–91) | 85 (80–92) | 78 (73–86) | 0.07 |
| Norepinephrine Dose (mcg/kg/min) (*n* = 31) | 0.1 (0.1–0.3) | 0.1 (0.1–0.3) | 0.2 (0.1–0.5) | 0.3 |
| CO (L/min) | 4.1 (3.4–5.3) | 4.5 (3.8–5.4) | 3.6 (3.1–4.5) | 0.06 |

| | All patients (*n* = 31) | Success group (*n* = 20) | Unsuccess group (*n* = 11) | *p*-values |
|---|---|---|---|---|
| PPV (%) | 7 (5–12) | 6 (4–7) | 12 (8–25) | < 0.01 |
| SVV (%) | 8 (6–11) | 7 (6–9) | 10 (8–18) | 0.02 |
| Lactate (mmol/L) | 1.3 (0.9–1.9) | 1.3 (0.9–1.9) | 1.5 (0.9–1.8) | 0.8 |

**Correspondence:** C. Dupuis
***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001408

**Introduction:** The administration of corticosteroids in the acute phase of severe COVID-19 pneumonia decreases the risk of mortality, among others in critically ill patients. However, the effectiveness of this treatment has never been studied in previously immunocompromised patients.
**Objectives:** The objective of this study is to assess the impact of early administration of steroids in immunocompromised patients admitted to the ICU for severe COVID-19 pneumonia.
**Methods:** This is a retrospective multicenter study, including immunocompromised patients admitted for severe COVID-19 pneumonia, between 01.08.2020 and 31.08.2022, in one of the ICU participating in the multicenter Outcomerea database, or in the ICU of Créteil, Nantes, Strasbourg and Montpellier, in France.
The clinical and biological characteristics of the patients were collected at admission and during the ICU stay. Patients were classified according to their type of immunosuppression, namely cellular, humoral, corticoid, and monocytic.
The outcome criteria were mortality at day 60 and the occurrence of nosocomial infection in ICU at day 60. Single- and multivariate survival analyses were performed.
The study was approved by the SRLF ethics committee.
**Results:** 362 patients were included, 310 of whom were receiving corticosteroids. Patients in the corticosteroid group had more cardiovascular comorbidities, were less severe (SAPS II: 38 [30; 47] versus 43.5 [33; 56.5], $p < 0.01$), had more nosocomial infections (24.2 vs 1.9%, $p < 0.01$), a longer ICO length of stay (11 [6; 19] vs 7 [4; 14], $p < 0.01$), but a similar death rate at day 60. Corticosteroid administration was not associated with an increased risk of death either in the entire cohort or by immunosuppression subgroups. Corticosteroids were associated with an increased risk of nosocomial infections (subHR = 1.98, CI 1.28; 3.05).
**Conclusions:** The protective effect on the death of corticosteroids is not found in immunocompromised patients. Corticosteroids were associated with an increased risk of nosocomial infections. These results require confirmation.

**Topic:** Infections and prevention

**Introduction:** Constrained by the limited resources and the high patient load in the early days of COVID-19 some intensive care units adopted prone positioning keeping the abdomen flush with the surface (flat prone) in mechanically ventilated patients with ARDS. Theoretically, higher peak airway pressures are expected in this position, due to restricted diaphragm motion, compared to the standard practice of suspending the abdomen (suspended prone) using thoracic and pelvic elevators/bolsters. Currently, no empirical evidence quantifies the difference in peak airway pressures or compliance between the flat prone and suspended prone positions, neither in patients with ARDS nor in healthy lungs.
**Objectives:** To determine the difference in peak airway pressures between flat prone and suspended prone in mechanically ventilated patients with healthy lungs.
**Methods:** Twenty-four adults without clinically apparent respiratory disease, presenting for percutaneous nephrolithotomy (PNL) were recruited. This population was selected as the standard positioning in PNL is flat prone in our institute. After informed consent general anaesthesia was administered using fentanyl, propofol and atracurium followed by endotracheal intubation with 6 ml/kg body weight of tidal volume, 12 breaths/min and positive end-expiratory pressure of 5 cmH2O in Volume controlled ventillation. The subjects were randomly allocated (1:1, concealed) to either sequence SF—suspended prone (period 1) followed by flat prone (period 2) or to sequence FS—flat prone (period 1) followed by suspended prone (period 2). Variables were measured at the 5th minute following each position change ensuring a train of four count of zero. Five minutes after intubation

the subject was placed in prone 1 (period 1), supine position for 5 min (washout period) and then in prone 2 (period 2). Peak pressures and compliance were analysed using a linear mixed effects model accounting for repeated measurements (repeated measures ANOVA) with terms included for sequence (FS vs SF), period (2 vs 1) and treatment (flat vs suspended prone).

**Results:** All 24 subjects were included in the analysis. Comparing the flat prone position to the suspended prone the difference in peak pressure was 0.08 cmH2O (95% CI, − 0.67 to 0.83, $p = 0.82$) and compliance was 0.17 ml/cmH2O (95% CI, − 2.20 to 2.54, $p = 0.89$). There were no significant period or sequence effects. There was no significant imbalance in baseline parameters or differences in the oxygen saturation, end-tidal carbon dioxide, exhaled tidal volume, blood pressure and heart rate at any time point. There were no perioperative adverse events (hypoxemia, barotrauma or surgical).

**Conclusions:** In mechanically ventilated non-obese adults with normal respiratory function, the peak airway pressure and lung compliance appear to be unaffected by whether the abdomen is suspended or flush with the surface in the prone position. This finding might, however, be different in patients with ARDS.

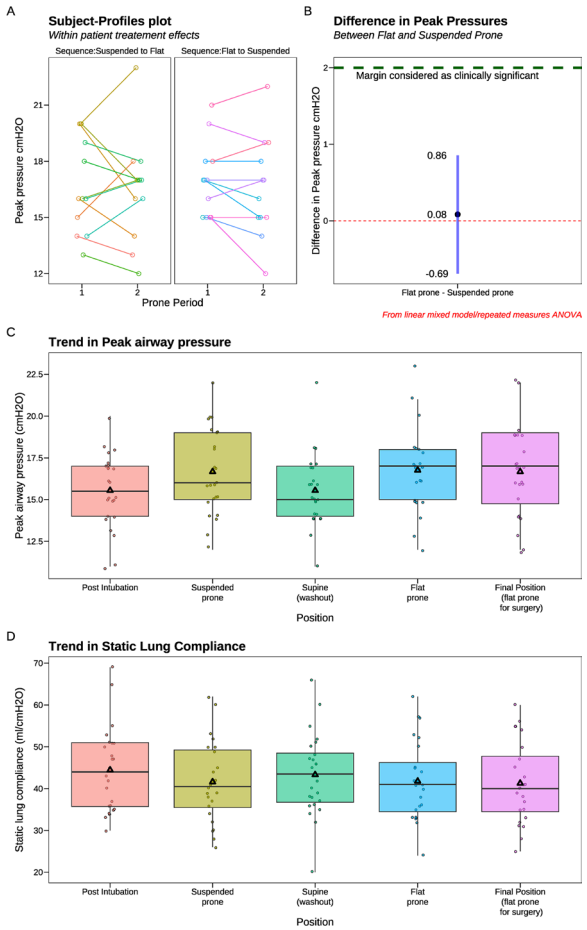

**Figure (abstract 001409)** (A) Subject profiles plot showing individual peak pressures by sequence and period; (B) Difference in peak pressure between suspended and flat prone positions; (C) Trend in peak airway pressures; (D) Trend in static lung conpliance; (C and D -includes all patients and are agnostic of sequence of positioning; triangles represent mean):

**Introduction:** Critically ill survivors may develop cognitive impairment affecting one or more domains. (1) Underlying molecular mechanisms remain unclear and may be related to the acute response to injury. Early characterization of this biological response could help to identify patients at high risk of neurocognitive sequelae (2).

**Objectives:** To identify subgroups of patients at high risk of developing postICU neurocognitive sequelae using whole blood transcriptomics at ICU admission.

**Methods:** Critically ill COVID-19 patients admitted to the ICU were prospectively recruited. Patients with neurocognitive history or psychiatric diagnosis were excluded. Survivors were cognitively assessed at 3 (3mo) and 12 (12mo) months after ICU discharge using the Repeatable Battery for the Assessment of Neuropsychological Status, (RBANS, normal mean 100 ± 15) (3), Trail Making Test, Stroop test and Dual-task

test. Z-scores were used to determine the cognitive deficit in each domain. Whole blood transcriptomes were obtained at ICU admission. Latent class analysis (LCA) was performed to identify subgroups with different multidimensional cognitive scoring. Differences in clinical data and gene expression between groups and time points were assessed. Gene Set Enrichment Analysis (GSEA) was used to explore related pathways. All analyses were performed with R.

**Results:** 104 ICU survivors (63 [56–71] year-old, 26% female) were recruited. 41 patients completed 3mo follow-up and 73, 12mo follow-up. RBANS scored 86 (80–99) at 3mo and 92 (82–100) at 12mo ($p=0.36$). Using the classical approach (4), global cognitive impairment (GCI) was diagnosed in 36.58% of the patients at 3mo, and in 35.48% of the patients at 12mo. LCA identified two classes (Fig. 1A): Class 1 showed lower scores than Class 2 in all RBANS domains and in the global score at 3mo and at 12mo (Table 1) and in TMT and dual-task test. GCI was more frequently diagnosed in Class 1 at 3mo (51.85% vs 7.14%, $p=0.01$) and at 12mo (64.29% vs 11.76%, $p<0.001$). Class 1 exhibited significantly higher IL-6 serum levels (94 [22–262.25] vs 24.5 [13.5–131.25], $p=0.02$) and lower peripheral leucocyte count (7260 [5675–9950] vs 9430 [6350–11770], $p=0.04$), at ICU admission. There were no other significant differences between classes across clinical variables. Differential gene expression analysis between classes revealed 34 downregulated and 3 upregulated genes (adjusted $p$-value < 0.05) ( Fig. 1B). Pathways related to activation of the innate immune response, and mTOR signalling were found in GSEA.

**Table 1 (abstract 001411)** Comparison of clinical characteristics between classes within the study cohort. Values shown as absolute count (percentage) or median (interquartile range)

| Variable | Class 1 *n* = 67 (64.42) | Class 2 *n* = 37 (35.57) | *p*-value |
|---|---|---|---|
| Age (years) | 66 (58–74.5) | 61 (55–69) | 0.087 |
| Sex (male) | 53 (79.10) | 24 (64.86) | 0.16 |
| Intubated at admission | 49 (73.13) | 25 (67.57) | 0.652 |
| Total RBANS 3mo | 83 (77.5–90.5) | 100.5 (95.25–106) | < 0.001 |
| Total RBANS 12mo | 83 (77–87.5) | 100 (96.25–105.75) | < 0.001 |
| Immediate Memory 3mo | 78 (71–84) | 97 (88.5–104.5) | < 0.001 |
| Immediate Memory 12mo | 76 (65–83) | 100 (90–103) | < 0.001 |
| Visuospatial/Constructional 3mo | 107 (101.5–117.25) | 116 (109–126) | 0.013 0.013 |
| Visuospatial/ Constructional 12mo | 105 (92–116) | 110.5 (100–121) | |

**Conclusions:** Transcriptomic profiling in whole blood samples at ICU admission may help to identify patients at high risk of postICU cognitive sequelae. Activation of innate immune response and dysregulation of the mTOR pathway could be involved in the development of cognitive impairment in critically ill survivors.

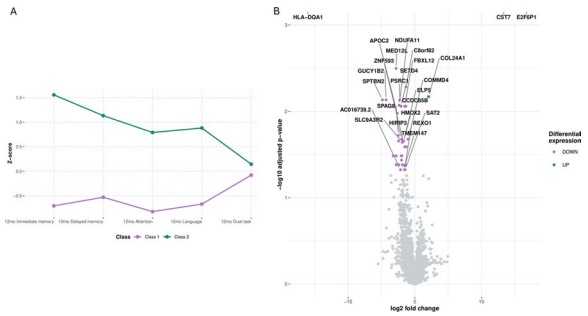

**Fig. 1 (abstract 001411)** A. Volcano plot with differentially expressed genes (adjusted $p$-value < 0.05) between latent classes. B. Profile plot of two patient classes identified according to cognitive domains evaluated at 12mo follow-up, using a latent mixture analysis. Values show means in each variable used for classification for each class (after normalization, Z-scores)

**Introduction:** Acute respiratory failure is one of the main causes of admission to the ICU in hematological patients and is associated with high mortality.

**Objectives:** To describe the characteristics of hematological patients admitted to the ICU of a tertiary center with a diagnosis of respiratory failure, their mortality and associated factors.

**Methods:** Retrospective study (2009–2020) including hematological patients admitted to the ICU for respiratory failure. Demographic and clinical data were obtained from medical records. Quantitative variables: mean ± SD or median (IQR25-IQR75); categorical variables: absolute value (%). Statistical analysis: Fisher's exact test for categorical variables and Mann–Whitney test for continuous variables.
**Results:** During the study period, 85 hematological patients were admitted for respiratory failure. Mean age: 55 (46–64) years; 55 (64.7%) males. Mean APACHE II score: 15 (4–30) points. Principal hematological diagnosis: acute leukemia; 50.6% ($n=43$) followed by lymphoma: 21.2% ($n=18$); plasma cell dyscrasia; 9.4% ($n=8$); chronic lymphocytic leukemia: 8.2% ($n=7$) and aplastic anemia: 7.1% ($n=6$). 67% ($n=57$) were hematopoietic stem cell transplant recipients (89% allogeneic). 62.4% of patients ($n=53$) required mechanical ventilation within the first 24 h. Median P/F ratio on admission: 110 (87–110). 56.5% patients ($n=48$) required norepinephrine and 17.7% ($n=15$) renal replacement therapy. Microbiological isolation was performed in 43.5% of patients. ICU mortality was 37.7% (32) and at 6 months after ICU admission 63.1% (56). Acute leukaemia diagnosis (95% vs. 35%, $p$ 0.04); APACHE II score < 15 and > 15 (33% vs. 95%, $p$ 0.02), and mechanical ventilation within the first 24 h (100% vs. 4%, $p$ 0.00) were associated with increased mortality. No significant differences between allogeneic transplant recipients (64%) and non-transplant recipients (54%) were found. Hemodynamic failure (73% vs 50% $p$ 0.50), renal failure at ICU admission (55% vs 87% $p$ 0.55) and positive microbiological isolation (56% vs.68% $p$ 0.82) were not associated with mortality.
**Conclusions:** In our series, acute leukemia diagnosis and early mechanical ventilation were the factors associated with mortality in hematological patients admitted to ICU for respiratory failure.

**Topic:** Haematologic-oncologic issues in the ICU

**Introduction:** Peripheral clocks in the liver have fundamental roles in maintaining liver homeostasis, including the regulation of energy metabolism and the expression of enzymes controlling the absorption and metabolism of xenobiotics. Clock dysfunction accelerates the development of liver diseases such as fatty liver diseases, cirrhosis, hepatitis and liver cancer, and these disorders also disrupt clock function. The liver clock is a robust oscillator and is at the centre of the cross-talk between the circadian timing system and metabolism. Abnormalities in such cross-talk play a role in the pathogenesis of fatty liver and the vicious circle underpinning its progression. Disruption of the liver clock, despite its prominent role in nutrient processing, does not affect the rhythmicity of clocks in other peripheral tissues. Yet, unexpectedly, liver-clock disruption strongly modulates the transcriptional rhythmicity of peripheral tissues, primarily during daytime feeding.
**Objectives:** Description of diurnal and nocturnal oscillations in the mortality of ICU patients hospitalized with liver cirrhosis, analysis of the peak hours of mortality at the same time to emphasize the most critical intervals to ensure appropriate therapy to prevent mortality.
**Methods:** A retrospective study was conducted (January–December 2023, ICU, IMSP SCM "Sf.Treime") on a group of 70 patients who died with decompensated liver cirrhosis in the ICU, with an average age of 63.04 ± 2.35 years, of which women 45.79% ($n=32$) and men 54.20% ($n=38$).
**Results:** Following the analysis, it was observed that mortality followed a biphasic circadian pattern. The peak of mortality was highlighted in the following peak hours: 00:00–01:00. 19:56% ($n=9$), 04:00–05:00 10.86% ($n=5$), 12:00–13:00 13.04% ($n=6$), 16:00–17:00 17.39% ($n=8$), 20:00–22:00 19.56% ($n=9$). At the same time, it was observed the peak time when more young people die with an average age of 41.35 ± 2.67 years, these being 17:00–19:00 8.69% ($n=4$). Moreover, time intervals where no deaths were recorded were 03:00–04:00, 10:00–12:00, 23:00–00:00.
**Conclusions:** In this study, the circadian pattern of mortality in intensive care patients was documented. Again, our study emphasized the importance of preventing in-hospital mortality by introducing appropriate medical care at a certain time of day. A better understanding of such abnormalities may help improve the management of decompensated cirrhosis.

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001414

**Introduction:** Diaphragm dysfunction and atrophy may occur in patients under Invasive Mechanical Ventilation (IMV) [1, 2], and can impact prognosis and clinical outcomes [3, 4]. Sepsis, a major risk factor, contributes to both diaphragm dysfunction [3, 5], and systemic muscle wasting [6]. Diaphragm Ultrasound (DUS) offers non-invasive assessment and has demonstrated significant utility and accuracy in detecting diaphragm dysfunction across various clinical scenario [7, 8]. Recent advancements in DUS include Shear-Wave Elastography (SWE), measuring Diaphragm Shear Modulus (SMdi) to assess tissue stiffness. This integration with biomechanics enhances diaphragm tissue evaluation. This becomes particularly relevant within the framework of the notion of diaphragm "myotrauma" [9].
**Objectives:** Our primary aim is to observe end-expiratory SMdi and Diaphragm Thickness (Tdi) over consecutive days in early-stage septic shock patients under IMV, particularly within the first five days after Intensive Care Unit (ICU) admission. We also aim to investigate the relationship between these DUS markers over time and their dependence on fluid balance and Positive End-Expiratory Pressure (PEEP) levels.

**Methods:** Preliminary analysis of a prospective observational study (Ethics Committee 2020–00452, NCT04550143) [10], in a mixed ICU. Eligibility was assessed within 24 h after ICU admission. Inclusion criteria: adult patients with septic shock, SOFA score ≥ 8, blood lactate > 2 mmol/L, expected > 48 h of IMV and > 5 days ICU stay. Data analysis included daily assessment of right-sided DUS at end-expiration, from ICU admission until liberation from IMV or day 5. Tdi (cm) was observed with ultrasound B-Mode and calculated between two parallel hyperechogenic layers, observed between 8 and 10th intercostal space. At the same region, SMdi was assessed with a targeted acquisition frequency of 2 Hz. Breath-by-breath analysis was performed offline and three images for each Tdi and SMdi were recorded. The mean value for both DUS markers was taken into analysis. The data are expressed as mean (standard deviation), median (interquartile range), frequencies and correlation coefficient (95% confidence interval). Paired sample *t*-tests used for day-to-day differences. The average correlation between SMdi and Tdi over time was estimated by computing correlation coefficients across time for each participant. The previous was replicated to test the association between DUS with fluid balance and PEEP.

**Results:** Nineteen septic shock patients were analyzed, thirteen reaching day 5 under IMV. Characteristics: 57.9% male, mean age 61.5 years (13.85), mean BMI 28.2 kg/m$^2$ (5.28). Median SAPS II, APACHE II, and SOFA scores at ICU admission: 72 (68–77), 35 (28–36), and 11 (9–11). Main infection sources: abdominal (57.9%) and respiratory (36.8%). Median time from ICU admission to first ultrasound: 1015 min (355.953). As depicted in Fig. 1, Tdi decreased significantly from day 1 to day 2 (mean − 9.3% (15.47), $p < 0.019$; $n = 19$); Tdi continued to decline until day 5, albeit with a less pronounced slope. SMdi increased over time, notably at day 4 (+ 40.1% (51.84), $p < 0.033$; $n = 17$). Over time, SMdi demonstrated no significant association with Tdi (− 0.363, − 0.642 to 0.003; $n = 17$), although the significance threshold was nearly reached. Fluid balance exhibited a moderate positive association with SMdi (0.410, 0.330 to 0.484; $n = 17$), while with Tdi (− 0.122, − 0.456 to 0.241; $n = 18$) no significant association was observed. Similarly, no significant association of PEEP levels with either DUS marker was found.

**Conclusions:** In this study, septic shock patients on IMV showed early significant atrophy nearing the clinically relevant 10% threshold in Tdi. In contrast, SMdi, reflecting tissue biomechanical changes, increased over days peaking later than Tdi. The absence of SMdi-Tdi correlation suggests distinct muscle characteristic assessment, emphasizing complementarity. Structural muscle changes assessed by SMdi appear to be influenced by fluid balance.

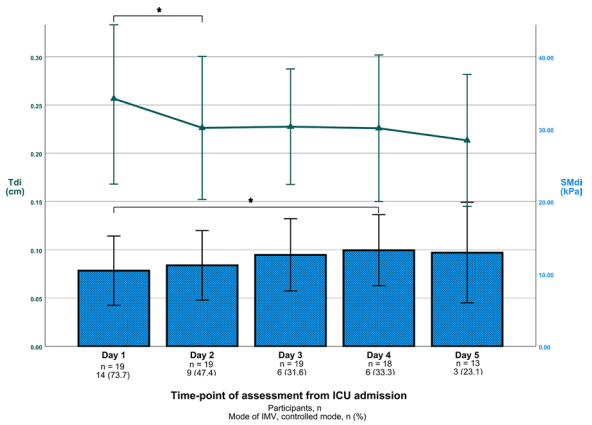

**Fig. 1 (abstract 001414)** Graphical representation of the temporal changes in diaphragm thickness (Tdi) and shear modulus (SMdi) over the five-day follow-up period among mechanically ventilated patients with septic shock in the intensive care unit (ICU). Diaphragm thickness (Tdi) is presented as a line chart, indicating a consistent decrease throughout the observation period. Notably, a more pronounced atrophy is observed between day 1 and day 2 of the assessment. In contrast, shear modulus (SMdi) is depicted as a bar chart, showing a progressive increase over time, with a notable surge particularly evident on day 4 of the assessment. Data are plotted as mean values and standard deviation (SD) represented by error bars. Statistical significance (*$p < 0.05$) is provided concerning day 1 of assessment

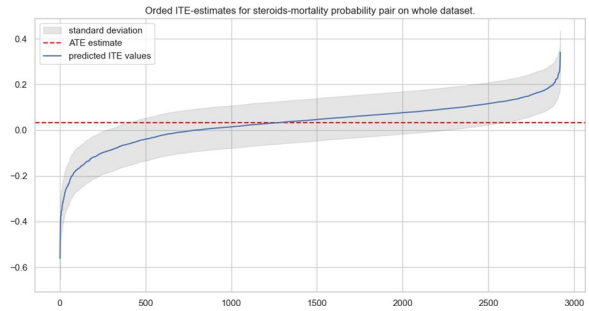
***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001415

**Introduction:** Sepsis patients often require organ support in the Intensive Care Unit (ICU), illustrating the clinical burden of the disease. Early and appropriate treatment is crucial for alleviating these issues. However, clinical trials are inconclusive about the usage of high-dose steroids. Using deep learning within a causality framework, we aimed to identify a subpopulation of sepsis patients that respond to high-dose steroids with improved survival rates.
**Methods:** Data for model development was extracted from the AmsterdamUMCdb database. 19 predictors from the first 24 h of admission were extracted. Initiation of high-dose steroids within 72 h of admission was defined as the intervention. The outcome was the probability of 28-day mortality. A treatment agnostic representation network (TARNet) was trained to estimate the individual treatment effect (ITE). A cutoff of 10% was used to classify steroid responders.
**Results:** 2930 admissions of AmsterdamUMCdb were eligible according to the Sepsis-3 criteria. 1378 were assigned to the intervention group and 1542 to the control group. Internal validation of the predictions of the observed outcomes showed an AUC of 0.79. An AUC of 0.70 was achieved with external validation using MIMIC-IV. Based on the estimated reduction of predicted mortality, a distinction was made between steroid responders ($n = 245$), non-responders ($n = 2098$), and those predicted to be harmed by steroids ($n = 577$). Steroid responders were characterized by a more significant metabolic acidosis.
**Conclusions:** Clinical profiles of steroid responders and 'harmers' were identified using a causal deep-learning model with large and highly granular ICU databases. Prospective evaluation and implementation testing in different healthcare settings is therefore a worthwhile approach for future investigations.



**(abstract 001415)** Ordered ITE estimates for steroids-mortality probability pair on the whole dataset. The x-axis represents the 2930 admissions from the data set. The y-axis represents the ITE, showing the ITE per patient for high-dose steroids. The Averaged Treatment Effect (ATE) is defined as the mean of all ITEs

**Topic:** Sepsis

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001416

**Introduction:** Traumatic brain injury (TBI) not only causes localized damage but also disrupts the complex network of connections within the brain. (1) These disruptions can have profound consequences for cognitive function and recovery. Graph theory provides a powerful mathematical framework for analyzing brain networks. (2) Metrics derived from graph theory quantify properties like network integration and segregation.
**Objectives:** To examine brain network topology on functional MRI in severe TBI patients.
**Methods:** In this prospective cohort study patients with isolated severe TBI (sTBI) admitted to neuro-intensive care units, between 2018 to 2022, were recruited. In sTBI patients, we used functional MRI and graph theory to examine brain network topology. We compared patients who survived ("Alive") vs. those who did not ("Dead") and correlated network measures with the Glasgow Outcome Scale (GOS) at one year.
**Results:** A total of 32 patients were recruited during the study period, of which 29 subjects were included in the final analysis whereas three subjects were excluded due to movement. Graph theory analysis revealed significant differences between Alive and Dead groups in clustering coefficient, path length, small-worldness, local and global efficiency, participation coefficient, and modularity across various network densities (Fig. 1). Nodal clustering coefficient in most brain regions correlated positively with GOS scores, indicating a potential link between integrated local networks and better outcomes (Table 1). Notably, the thalamus showed a negative correlation with GOS.
**Conclusions:** Our findings demonstrate the utility of graph theory in characterizing TBI-related network changes. Variations in local network efficiency and integration may relate to patient outcomes, providing potential targets for future investigation and intervention.

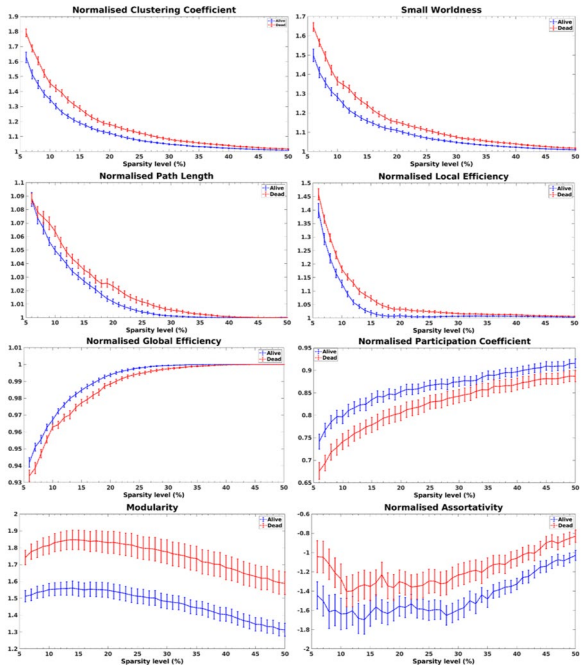

**Fig. 1 (abstract 001416)** Clustering coefficient (CC) of various parameters between dead vs alive patients

**Table 1 (abstract 001416)** Correlation between the Glasgow Outcome Scale (GOS) and the nodal clustering coefficient across various brain regions.

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001417

**Introduction:** Prevention and treatment of hypoglycemia is an important part of glucose control in the critically ill. Our ICU has been using a computerized glucose control decision support system (GRIP) over the past 20 years. Together with GRIP, the nurse determines the next insulin infusion rate and the timing of the next glucose measurement [1]. In case of a glucose level < 3.5 mmol/L, GRIP also requests to notify a physician. The incidence of insulin-associated hypoglycemia (IAH) with GRIP in our population is low, and more than a third of hypoglycemias are "spontaneous" hypoglycemia (SH) [2], i.e. not associated with insulin use. SH is strongly associated with (acute) liver failure [3] and requires continuous concentrated glucose infusion without a bolus, as stated in international guidelines [4] as well as our local protocol. Multi-organ failure in the critically ill typically does not start with diagnosed liver failure. Accordingly, SH developing during progressive organ failure may not be recognized as a sign of liver failure and thus not appropriately acted upon.
**Objectives:** Characterize documented clinical actions in case of hypoglycemia (IAH or SH) and examine awareness in ICU nurses and ICU physicians with respect to SH and its treatment.
**Methods:** A retrospective data analysis was performed on 2 × 50 adult patients who experienced IAH and SH respectively, between January 2018 and May 2021. We examined if the interpretation was correct and if appropriate action was taken in the case of IAH or SH. An anonymous survey was also performed among ICU nurses and ICU physicians with regard to their appreciation of hypoglycemia.
**Results:** Two patients were excluded because their hypoglycemia originated outside the ICU, leaving 50 patients with IAH and 48 with SH. The hospital mortality was 40% (AIHI) and 71% (SH), respectively ($P = 0.003$). In 51% of hypoglycemias the local protocol was followed, indicating correct treatment and registration in the patient file. In 29 patients (60%) a glucose bolus infusion was given, while not advised by the protocol, while in 12 patients (25%) with SH no continuous glucose infusion was started, although this was advised by the protocol. Hypoglycemia was recorded in the electronic patient notes in 46% by physicians and 37% by nurses and a differential diagnosis was only recorded in 27%.
The response rate to the survey was 31% (57 nurses and 30 physicians). Virtually all (97%) recognized insulin as a potential cause of hypoglycemia, while 75% (64) also considered other causes. When SH is diagnosed, only 61% of the physicians would initiate a continuous glucose infusion. Given these results, we initiated an additional information campaign in our department with respect to IAH and SH.
**Conclusions:** Spontaneous hypoglycemia in ICU patients indicates a severe condition. We observed a tendency to approach spontaneous hypoglycemia similar to insulin-associated hypoglycemia, both in diagnosis and in treatment. This might be related to the prominent role of computer control in glucose regulation in our department. However, in other institutions there may be also insufficient awareness that a continuous concentrated glucose infusion, and not a bolus is the appropriate action in spontaneous hypoglycemia.

**Introduction:** Patients who require activation of the massive hemorrhage protocol (MHP) for hemorrhagic shock have a high mortality. Knowing the characteristics of our patients could allow us to improve care.
**Methods:** Retrospective descriptive study that includes 69 patients transfused under MHP of mixed cause in the Guadalajara Hospital from 2022 to 2024. We filtered the activation of the MHP for transfusion of 3 or more red blood cell units in the first hour. Epidemiological, clinical, and analytical variables related to the transfusion and follow-up until discharge from the hospital or death, failing that, are collected. Quantitative variables are presented by their median and

interquartile range and qualitative variables as proportions in absolute number and percentage. Differences between survivors and deceased were analyzed by statistical analysis with the Chi-square tests for qualitative variables or the Student *t* test for quantitative variables. The required significance threshold was 0.05.

**Results:** A total of 69 patients were included with a diagnosis of severe trauma ($n=21$), digestive bleeding ($n=10$), coagulopathy of medical origin ($n=7$), gastrointestinal surgery ($n=16$), vascular surgery ($n=10$) and urogynecological surgery ($n=5$). The average age is $63\pm17$ years, with 63% men in the sample. In the univariable analysis of quantitative variables of survivors and deaths patients, the systolic blood pressure was 90 mmHg Vs 77.5 mmHg ($p=0{,}039$), pH 7.29 Vs 7.18 ($p=0.016$) and lactic 3.4 Vs 6.4 ($p=0.006$), were statistically significant. Regarding the blood products transfused, there were no significant differences between them. A total of 30 h in mechanical ventilation and 8.5 h of length of hospital stay in which no analysis was performed to avoid survivorship bias. A multivariable analysis was performed using the statistically significant variables (pH, SBP and lactic acid), with an association for systolic blood pressure (OR = 1.037, CI 95%: 1.007–1.068) and lactic (OR = 1,161; CI 95%: 1017–1325). In the survival analysis using the Kaplan–Meier curve, we observe a mortality of 40, 57% ($n=28$) at 30 days. Different causes of mortality were identified: in the first hours–days, refractory shock and rebleeding, to die of multiple organ failure in the following weeks (picture 1).

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001419

**Introduction:** The creation of specific ischemic stroke units in hospitals has changed the clinical characteristics and morbimortality of those patients who require admission to Intensive Care Units (ICU).

**Objectives:** The aim of this study was to describe the clinical characteristics of patients with ischemic stroke who require admission to the Intensive Care Units (ICU) of a third-level hospital with a specific Stroke Neurological Unit.

**Methods:** Retrospective, observational study performed in ischemic stroke patients admitted to the ICU of H.G.U Gregorio Marañón between 2022 and 2023 years. We collected epidemiological data, comorbidities, stroke risk factors, severity scores (APACHE II, GCS and NIHSS: National Institute of Health stroke scale), cerebral artery affected, specifics treatment used, organic support measures used, complications during ICU stay and outcome assessed using the modified Rankin scale (mRS).

Descriptive analysis was expressed as means with standard deviation for normally distributed quantitative variables, medians with interquartile range (IQR), for non-normally distributed variables, and percentages for categorical data.

**Results:** Fifty-seven patients were included, 53% were male, mean age was 68 yrs (59–78). Charlson Comorbidity Index 1 pts (0–3), any risk factor for stroke 84% with median 2 (1–4), highlighting: arterial hypertension 60%, dyslipidaemia 45%, smoker 37%, diabetes mellitus 35%, heart disease 30%, obesity 19%, previous stroke 19% and atrial fibrillation 17%. Severity scores: APACHE II $20\pm6$ pts, GCS $10\pm3$ pts, NIHSS $13\pm7$ pts. The anterior cerebral arterial circulation was the most frequently affected (62%) and both circulations will be affected in 7% of cases. The frequency of vessel involvement was: middle cerebral artery (68%, left side 43%), internal carotid artery (26%, left side 21%), posterior cerebral artery (21%, left side 12%), basilar artery (18%) and vertebral artery (14%). The treatment applied was fibrinolysis in 20% of cases and thrombectomy in 60%, performing both treatments in the same patient in 16% of cases, with a median time of 90 min (60–120). During ICU stay, the infectious processes were the most frequent complication complications (11% ventilator-associated pneumonia, 7% aspiration pneumonia, 5% catheter-related bacteraemia), followed by intra-cerebral bleeding (18%) ARDS (4%) and ventricular dysfunction (2%). 70% of patients needed mechanical ventilation, with an average time of 2 days (0–5), and 16% of patients underwent tracheostomy for respiratory support removal. The mean ICU stay was 4 days (2–10), with 36% mortality. The mean in-hospital stay was 10 days (4–18),

with 41% mortality. Regarding the neurological outcome, 65% of patients obtained an unfavorable prognosis (mRS 4–6), that is, dying or severely affected in terms of capacity.
**Conclusions:** There was a significant mortality and a large number of complications in patients with ischemic stroke who require admission to ICU. In addition to mortality, most patients have an unfavorable prognosis assessed using the modified Rankin scale.

*Intensive Care Medicine Experimental* 2024, **12 (suppl 1)**: 001420

**Introduction:** The xanthine family includes the drug theophylline, which is utilized for its bronchodilator properties. However, its prescription is decreasing due to its extremely limited therapeutic spectrum. Accidental or deliberate theophylline intoxication is uncommon but can have significant consequences in certain situations.
**Objectives:** The aim of our study was to study the correlation between clinical manifestations and plasma levels of theophylline intoxication.
**Methods:** All patients admitted to the intensive care unit for acute theophylline poisoning over an eleven-year period (2013–2023) were included in this retrospective analysis. In patients admitted for theophylline intoxication, the relationship between plasma dose and clinical symptoms was examined using Pearson correlation. In our hospital's toxicology lab, theophylline was measured (Standard Value = 4–12 mg/l).
**Results:** A total of 103 individuals were admitted due to theophylline intoxication during the study period. The patients were primarily female and ranged in age from 17 to 28 years old, with a median age of 20. Asthma was present in 19 instances (18.4%) and chronic obstructive lung disease in 9 cases (8.7%) of the respiratory history. Ninety-three instances (93%) had voluntary intoxication, and the median interval between intake and admission was five hours [3–9]. There were 92 instances (89.3%) with digestive symptoms, 90 patients (87.4%) with tachycardia, 21 patients (20.4%) with tremors, 10 patients (9.7%) with agitation, 4 patients (3.9%) with seizures, and 7 patients (6.8%) with shock. 51 patients (59.3%) had metabolic acidosis, with a mean bicarbonate level of $16.1 \pm 3.45$ mmol/L. Lactatemia was $4.25 \pm 2.41$ mmol/L on average. 84 patients (82.4%) had hypokalaemia at admission, and 37 cases (36.3%) had electrical symptoms. 38 mg/L was the median theophyllin level [28.7–60].
Thirteen patients (12.6%) experienced severe intoxication, defined as > 100 mg/L, while forty patients (38.9%) had mild intoxication, defined as between 20 and 40 mg/L.
In 60 cases, the usage of beta blockers was recommended (58.5%).
Shock risk was correlated with severe intoxication ($p = 0.000$; OR = 2.16), with a 95% confidence interval (CI = [1.2; 3.9]).
Theophyllinemia and heart rate were shown to be closely correlated ($p = 0.000$), and there was also a correlation between theophyllinemia and bicarbonate levels and kalemia ($p$ values of 0.009 and 0.001, respectively).
In our study group, there were no recorded deaths.
**Conclusions:** The degree of theophylline intoxication is correlated with tachycardia, hypokalaemia, and metabolic acidosis.

**Healthcare professionals' knowledge and practice of and attitudes towards pharmacovigilance in Alexandria, Egypt: a cross-sectional survey**
S. Abdelmonem[1], I. Elsayed[2]
[1]ICU, صاخلا امبا ىفشتسم, Abha, Saudi Arabia, [2]Medical statistics, Medical Research Institute, Alexandria, Egypt
**Correspondence:** S. Abdelmonem
*Intensive Care Medicine Experimental* 2024, **12 (suppl 1)**: 00122

**Introduction:** Pharmacovigilance as a concept is still new to healthcare professionals (HCPs) in Arabian countries. Morbidity and mortality related to adverse drug reactions (ADRs) are health problems that affect both adults and children worldwide, greatly impacting patients' health and the costs of healthcare services. Good pharmacovigilance programs can quickly recognize both risks and factors that reduce or prevent harm.
**Objectives:** Our objective was to compare HCPs' knowledge and practice of and attitudes toward pharmacovigilance in Alexandria, Egypt.
**Methods:** A cross-sectional survey comprising 20 questions was completed by 547 pharmacists and physicians in three different health sectors between August 2017 and March 2018. Data were analyzed using SPSS version 20. Bivariate analysis was conducted using the Chi-squared test and multivariate logistic regression. The main outcome was measuring HCPs' knowledge and practice of and attitudes towards pharmacovigilance.
**Results:** In total, 232 (42.4%) physicians and 315 (57.6%) pharmacists completed the survey. The odds of having a high level of knowledge of and a positive attitude towards pharmacovigilance were nearly six times higher among pharmacists than among physicians (odds ratio [OR] 6.60 [95% confidence interval {CI} 2.31–18.85] and OR 5.66 [95% CI 2.26–14.15], respectively). The odds of high levels of pharmacovigilance practice for pharmacists were more than twice as high as those for physicians (OR 2.62 [95% CI 1.35–5.05]). Major barriers to reporting ADRs were lack of time (71%) and difficulty deciding whether or not an ADR occurred (48%).
**Conclusions:** In Egypt, physicians had less knowledge and less positive attitudes towards pharmacovigilance than pharmacists. This limited knowledge among physicians could be affecting the practice of ADR reporting. Health authorities in Egypt should initiate educational interventions and a practical training program primarily targeting physicians to enhance a culture of pharmacovigilance and drug safety in the country.

**Introduction:** Ischemic stroke is a common neurological emergency that is associated with high rates of morbi-mortality. With the appearance of reperfusion treatments and specific stroke units, the ICU admission of these patients has decreased.
**Objectives:** The purpose of this study was to identify risk factors for an unfavourable prognosis in patients with ischemic stroke who require admission to the ICU.
**Methods:** Retrospective, observational study performed on patients admitted to the ICU of H.G.U Gregorio Marañón with ischemic stroke between 2022 and 2023 years. We collected epidemiological and clinical data, scoring systems (APACHE II, GCS and NIHSS: National Institute

of Health stroke score), cerebral artery affected, specific treatment used (fibrinolysis and/or thrombectomy), organic support measures used and complications during ICU stay. The prognosis was valued by the modified Ranking scale (mRS) (unfavorable prognosis 4–6 pts, that is, moderate-severe disability, severe disability and death).
Descriptive data were described as means with standard deviation for normally distributed continuous variables, medians with interquartile range (IQR) for non-normally distributed variables, and percentages for categorical data. The continuous variables were categorised according to the maximum discrimination point by the AUROC curve. A univariate and multivariate analysis was performed using logistic regression to determine the factors related to unfavourable prognosis.
**Results:** Fifty-seven patients were included, 53% male. Age 68 yrs (59–78). Charlson Comorbidity Index 1 pts (0–3), any risk factor for stroke 84% with a median 2 (1–4). Severity scores: APACHE II 20 ± 6 pts, GCS 9 ± 4 pts, NIHSS 13 ± 7 pts. The anterior cerebral arterial circulation was the most frequently affected (62%) and the middle cerebral artery was the vessel mostly occluded (68%). A specific treatment was applied in 82% of patients (thrombectomy 60%, fibrinolysis 20% and both 16%), with a median time of 90 min (60–120). The 70% of patients needed mechanical ventilation and 48% had any complications during ICU stay, highlighting: ventilator-associated pneumonia (11%) and cerebral bleeding (18%). Length of ICU stay was 4 days (2–10) and in-hospital stay 10 days (4–18). 65% of patients had unfavourable prognosis (mRS 4–6), including 41% of mortality.
In the univariate analysis, the results were: Age > 65 yrs (OR 2.33; 95% CI 0.74–7.27), ischemic stroke risk factors (OR 1.17; 95% CI 0.26–5.31), Charlson Index > 2 pts (OR 1.05; 95% CI 0.34–3.21), NIHHS > 16 pts (OR 2.34; 95% CI 0.59–9.20), APACHE > 22 pts (OR 3.73; 95% CI 1.10–12.65), GCS < 10 pts (OR 4.45; 95% CI 1.34–14.83), affected anterior circulation (OR 1.55; 95% CI 0.47–5.12), any specific treatment (OR 0.68; 95% CI 0.21–2.24), mechanical ventilation (OR 9,01; 95% CI 2.48–33.11) and ICU complications (OR 6.35; 95% CI 1.73–23.25).
Using multiple logistic regression, including the previous variables, the independent risk factor for unfavorable prognosis were: Age > 65 yrs (OR 8.06; 95% CI 1.02–63.59), mechanical ventilation (OR 7.66; 95% CI 1.14–51.28) and ICU complications (OR 10.38; 95% CI 1.57–68.71).
**Conclusions:** In our experience, a high percentage of patients with ischemic stroke who required ICU admission had an unfavorable prognosis. The independently factors associated with poor prognosis were age, mechanical ventilation and ICU complications.

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001424

**Introduction:** Stroke is a devastating and costly disease. That is the second leading cause of death worldwide and the first leading cause of long-term disability, making the prevention of stroke a global health priority. Stroke is preventable to a large extent due to modifiable risk factors. Although risk factors are well known, recent studies showed regional variations in the prevalence of risk factors.
**Objectives:** The aim of the study was to evaluate the risk factors for the occurrence of acute stroke, either hemorrhagic or ischemic, that required admission at critical care units among the Egyptian population at Alexandria Hospitals.
**Methods:** In this retrospective observational study, 1202 participants were recruited from critical care units, comprising 535 (44.5%) cases of acute stroke, 282 (23.5%) cases of hemorrhagic stroke, and 385 controls of different diagnoses. Data from all the patients were collected retrospectively by revising the medical record and patients' available medical data and then administered through a structured online questionnaire.
**Results:** Out of the studied cases, 817 cases of stroke were distributed: 60% of cases were males, 43% of cases were above 65 years old, 24% have family history of stroke, 83% were hypertensive, 60% were diabetic, 62% have ischemic heart disease, 51% have dyslipidemia, 60% were smokers, 35% have atrial fibrillation, 12% have renal disease, 18% have hepatic disease, 4% have vasculitis, 40% were obese, and 10% have psychiatric problems.
**Conclusions:** Hypertension is the most independent factor for the occurrence of stroke followed by atrial fibrillation and then smoking among the Egyptian population.

**Topic:** Neurointensive care

**Introduction:** While remaining as a leading cause of death among the pediatric population, national data regarding the trends in mortality among critically ill pediatric hemato-oncologic patients are lacking.
**Methods:** We analyzed the incidence and mortality trends of children younger than 15 years admitted to an intensive care unit (ICU) with a diagnosis of hemato-oncologic disease from 2009 to 2020 using the Korean National Health Insurance database. Trends in incidence and mortality of subgroups according to diagnosis (hematologic disease vs oncologic disease), admission department (medical vs surgical), use of mechanical ventilation, and use of vasopressors were evaluated. Multivariable logistic regression analyses were performed to estimate the odds ratio of in-hospital mortality according to admission year.
**Results:** Among 263,911 pediatric hemato-oncologic admissions, 6866 ICU admissions were identified. The overall in-hospital mortality of ICU admissions was 10.3%. There was a significant decrease in mortality from 12.6 in 2012 to 8.9% in 2020 (P-for trend < 0.01). In-hospital mortality decreased by 5.8% yearly in adjusted analysis ($P < 0.01$). The improvement in in-hospital mortality was more prominent among patients admitted to the medical department ($P$-for trend < 0.01, mortality decrease from 23.9 to 13.4%) and patients requiring organ support including mechanical ventilation ($P$-for trend < 0.01, mortality decrease from 32.6 to 19.0%) and vasopressors ($P$-for trend < 0.01, mortality decreased from 30.4 to 14.2%).
**Conclusions:** Mortality of critically ill hemato-oncologic children improved during the study period, and the improving trend was prominent in children with high treatment requirements.

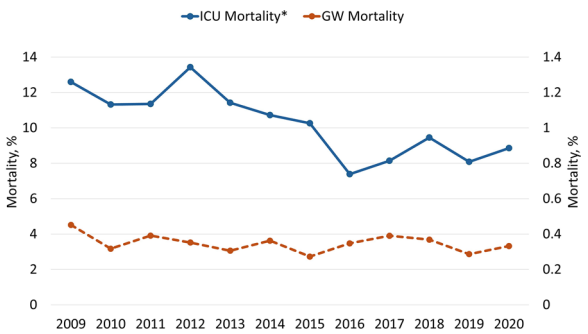

**Fig. 1 (abstract 001425)** Trends of in-hospital mortality among hematology-oncology patients. ICU = intensive care unit; GW = general ward. * Indicates P-for trend < 0.01

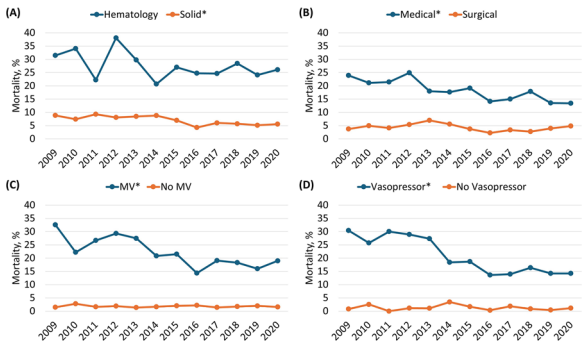

**Fig. 2 (abstract 001425)** Trend of in-hospital mortality of critically ill pediatric hemato-oncology patients in subgroups. ***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001426

**Introduction:** Septic shock is associated with endothelial dysfunction leading to arterial and venous dilation, alterations in regional blood flow distribution, and microcirculatory disturbances. Fluids and vasopressors are the key elements of the hemodynamic support. Vasopressin is recommended by 2021 Surviving Septic Shock guidelines1 as second-line vasopressor for patients presenting hypotension refractory to norepinephrine. The proposed cut-off defining refractory hypotension ranges from 0.25 to 0.5 mcg/kg/min but there is no clear indication on the timing of introduction.
**Objectives:** To analyze the optimal timing for the introduction of the second vasopressor in septic shock and evaluate its prognostic impact according to the doses of noradrenaline (NAD).
**Methods:** Observational, retrospective study conducted on patients admitted to the ICU of H.G.U Gregorio Marañón between January 2022 and December 2023. According to the established protocol, all patients received vasopressin (VAP) infusion when their dose of noradrenaline (NAD) exceeded 0.25 ug/kg/min. Epidemiological data, comorbidities, severity, clinical characteristics, organ support, and outcomes were collected.
Descriptive analysis is expressed as mean (SD) or median (IQR) for quantitative variables and percentages for qualitative ones. The impact on mortality of the NAD dose at which VAP was initiated was analyzed by simple logistic regression, and the dose with the best discrimination was determined by the area under the curve (ROC). Multivariate analysis by Cox regression adjusted for potential confounding factors was performed to determine its association with mortality. Survival analysis adjusted for the NAD dose at which VAP was initiated was conducted.
**Results:** 140 patients were included, 53% males. Age: 61 ± 15 years. Charlson Index: 2 (1–4). APACHE II: 23 ± 7, SOFA: 9 ± 3. Infectious focus: respiratory 54%, abdominal 21%, urinary 9%. The sepsis bundle was fulfilled within the first hour in 64% of patients. Antibiotic accuracy was achieved in 65%. Analytical data: pH in ICU 7.31 (7.26–7.41), lactate in ICU 5 ± 4. 75% required invasive mechanical ventilation (IMV) with a duration of 5 days (1–11). Time to NAD start from septic shock diagnosis: 3 h (2–6), time to VAP start from septic shock diagnosis: 8 h (6–11), NAD dose at VAP initiation: 0.5 ± 0.3 ug/kg/min. A 14% complication rate was observed in the series, with atrial fibrillation being the most frequent (8%). ICU days: 9 (5–14), hospitalization days: 14 (8–23). ICU mortality at 28 days: 39%.
In univariate analysis, the NAD dose at VAP initiation was associated with mortality (OR 0.02; 95% CI 0.01–0.04). The NAD dose at VAP initiation was able to discriminate prognosis (Area under the curve 0.929; 95% CI 0.88–0.97), with 0.40 ug/kg/min being the dose that best-discriminated mortality. By Cox regression, adjusted for age, comorbidity, severity, time to start vasopressors, lactate, sepsis bundle, and antibiotic accuracy, a dose of < 0.4 mcg/kg/min behaved as an independent mortality factor (OR 0.11; 95% CI 0.04–0.27).
**Conclusions:** In our experience, initiating vasopressin when intermediate doses of noradrenaline are reached could improve the prognosis of patients with septic shock.

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001427

**Introduction:** Acute Respiratory Distress Syndrome (ARDS) is currently treated by mechanical ventilation and in the most severe cases by extra-corporeal membrane oxygenation. As an alternative, total liquid ventilation (TLV) has been proposed to reduce ventilator-induced lung injury, ventilation-perfusion mismatch, lung atelectasis and lung debris accumulation. Until now, its effect on ARDS was evaluated in small animals, except for one sheep study (1). In the latter, total lung liquid volumes were not continuously monitored and initial lung filling was done with a high volume of breathable liquid (> 30 ml/kg). Here, we hypothesized that a new device for TLV can provide benefits while limiting pulmonary liquid volumes in large animals.
**Objectives:** Our goal was to demonstrate the feasibility of TLV in a swine model of life-threatening ARDS using a new device enabling TLV at lower lung volume by preventing airway collapse during expiration and continuous regulation of lung liquid volume.
**Methods:** Twelve swine (33 ± 2 kg) were anesthetized and instrumented for pulmonary and hemodynamic monitoring. ARDS was induced by one or two administrations of oleic acid (0.1 mg/kg) until the achievement of a PaO2/FiO2 < 100 mmHg. Animals were then allocated to protective gas ventilation (tidal volume [Vt] of 6 ml/kg, 100% FiO2, positive end-expiratory pressure = 5 cmH2O; Control group) or TLV with perfluorooctylbromide using a dedicated prototype (LV4B, Orixha®; Figure A-B) controlling tidal and end-expiratory liquid volumes (LqVt and EELqV, respectively). Respiratory rate, LqVt and EELqV were set within 4–6 cycles/min, 8–14 ml/kg or 12–30 ml/kg, respectively. After a maximum of 60 min following group allocation ("treatment phase in Figure C), surviving animals were euthanized for necropsy.
**Results:** Ten animals achieved inclusion criteria (PaO2/FiO2 < 100 mmHg) and were allocated to Control or TLV groups ($n = 5$ in both groups). They initially presented similar oxygenation, hemodynamics and respiratory mechanics alterations. After group allocation, 3/5 animals deceased prematurely in the Control group (60%), due to sustained hypoxemia (PaO2 < 50 mmHg) before the end of the 60 min of follow-up under protective ventilation (Figure C). Conversely, zero animals died prematurely during this treatment phase in the TLV group. These animals presented a trend toward better oxygenation than the surviving Controls (e.g., 50 ± 6 vs. 113 ± 63 mmHg of PaO2 in Control vs TLV at $t = 30$ min of follow-up, respectively). Blood CO2, pH, lactates or pulmonary and systemic hemodynamics were similar between groups in survivors. In the TLV group, LqVt, EELqV and respiratory rate averaged 12.6 ± 1.0 ml/kg, 22.9 ± 6.4 ml/kg, and 5.3 ± 1.0 breath/min at the end of the procedure, respectively. Histopathological examination of the lungs of all animals demonstrated a lower extent of inflammatory and congestion lesions in TLV vs Control ($n = 5$ group; Figure D).
**Conclusions:** TLV with this new device improved short-term survival and reduced lung injury in a swine model of life-threatening ARDS. This supports the need for further investigations with longer treatment duration.

### Impact of vasopressin on renal function in patients with septic shock

M. Artabe[1], R. Rocio[1], J. Cui[1], G. Castañeda[1], B. Asier[1], C. Alvarez[1], J. Cedeño Mora[1], P. García Olivares[1], C. Ramirez[1], N. Cango[1], A. Rodriguez[1]
[1]Intensive care unit, Gregorio Marañón General University Hospital, Madrid, Spain

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001428

**Introduction:** In 2015, it was estimated that there were more than 230,000 cases of septic shock with more than 40,000 deaths in the United States each year.1 In addition to treating the underlying infection, the mainstay of cardiovascular resuscitation in septic shock is intravenous fluids and vasopressor treatment. Norepinephrine is the recommended first-line vasopressor2 but, since a relative vasopressin deficiency in septic shock was described, there has been growing interest in the use of vasopressin as an adjunctive agent.3 Preclinical and small clinical studies have suggested that vasopressin may be better able to maintain glomerular filtration rate and improve creatinine clearance compared with norepinephrine.
**Objectives:** To analyze if the dose of noradrenaline (NAD) at which vasopressin (VAP) is initiated has an impact on renal function.
**Methods:** Observational, retrospective study on the impact on renal function in patients with septic shock treated with VAP as a second vasopressor drug associated with NAD in the ICU of H.G.U Gregorio Marañón, between January 2022 and December 2023. Epidemiological data, comorbidities, severity, clinical characteristics, organ support, and outcomes were collected.
Descriptive analysis is expressed as mean (SD) or median (IQR) for quantitative variables and percentages for qualitative ones. Univariate analysis was performed using Chi-square (RR) for qualitative variables and simple logistic regression (OR) for quantitative ones. Multiple logistic regression, adjusted for severity, to determine factors independently related to mortality.
**Results:** 140 patients, 57% male. Age 61 ± 15 years. Charlson Index 2 (1–4). APACHE II 23 ± 7, SOFA 9 ± 3. Medical pathology 95%, the most common infectious focus being respiratory (54%).
The sepsis bundle was completed within the first hour in 64% of patients. Antibiotic accuracy was achieved in 65%. Analytical data: pH in ICU 7.31 (7.26–7.41), lactate in ICU 5 ± 4. 75% required invasive mechanical ventilation with a duration of 5 days (1–11). Time to start NAD from septic shock diagnosis: 3 h (2–6), time to start VAP from septic shock diagnosis: 8 h (6–11), NAD dose at VAP initiation: 0.5 ± 0.3 ug/kg/min. Severe cardiac dysfunction was present in 14%.
Volume resuscitation: volume in the initial 24 h 4500 (3500–6000).
Diuresis and balances: first 24 h diuresis 1040ml (530–1482), positive balance in the first 24 h 94%, negative balance at 48 h only in 41%.
Preload optimization: preload was established to be optimized in 76% of patients before starting VAP.
Renal failure at 24 h from sepsis diagnosis: no ARF 25%, KDIGO I 31%, KDIGO II 19%, KDIGO III 25%, need for renal replacement therapy: 41%
ICU days 9 (5–14), hospitalization days 14 (8–23). ICU mortality at 28 days: 39%.
In univariate analysis, NAD dose < 0.4 mcg/kg/min at VAP initiation was associated with decreased renal failure in the ICU (OR 0.14; 95% CI 0.05–0.32), with developing ARF in the first 24 h of ICU (OR 0.12; 95%

CI 0.06–0.29), and with the need for renal replacement therapy (OR 0.14; 95% CI 0.05–0.27).
**Conclusions:** The use of Vasopressin when noradrenaline is at intermediate doses appears to decrease the incidence of acute renal failure in patients with septic shock.

### Prophylactic use of methylene blue (MB) in patients at high risk of vasoplegic syndrome after cardiopulmonary bypass

J.P. Torrez[1], D. Otsuki[2], A.E.L. Pontes[1], A.F. Sanchez[1], S.P. Zeferino[1], J.O. Auler Junior[1]
[1]Anesthesiology, Heart Institute of the Hospital das Clínicas of FMUSP, São Paulo, Brazil, [2]Anesthesiology, Clinical Hospital FMUSP, São Paulo, Brazil
**Correspondence:** J.O. Auler Junior
***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001429

**Introduction:** Vasoplegic or vasogenic shock syndrome is a common event after cardiopulmonary bypass surgery, characterized by low arterial pressure, unresponsive vascular collapse to high doses of vasopressors, and biochemical signals of cellular oxygen debt. Pathophysiology is related to the dysfunction of vascular smooth muscle cell contraction, activation of the complement cascade and the expression of pro-inflammatory mediators, adrenoreceptor desensitization, nitric oxide (NO) synthesis increase, cellular membrane hyperpolarization, dysfunction of the renin-angiotensin system, endothelial glycocalyx lesion and possible vasopressin synthesis decrease. Methylene blue (MB) actively inhibits NO synthase and the enzyme guanylate cyclase, preventing the accumulation of cGMP, and thus decreasing the vessels' sensitivity to cGMP-dependent vasodilators and restoring normal vascular tone. Most reports state that the MB is given after the vasoplegic syndrome is installed. We hypothesize that the prophylactic use of MB at the start of the bypass could decrease the number of vasopressor drugs, length of ICU stays, and secondary outcomes in patients with higher Euro scores and susceptibility to vasoplegia.
**Objectives:** We aimed to conduct a randomized, controlled clinical trial (110 patients) of high-risk for developing vasoplegic syndrome after bypass undergoing cardiac during routine valvar surgery.
**Methods:** The patients were randomized to control (normal saline) or MB (1 mg/kg/hour starting at the beginning of bypass lasting seven consecutive hours, totaling seven mg/k).
The size sample was calculated to reduce by 25% the vasopressors consumption over time at the $p$ level (5%) and statistical power of 80% (total number 110 patients). To this point, we have randomized 52 patients (26 control group and 26 MB group. Patients were selected from the routine valvar procedure surgeries with bypass. The inclusion criteria were EURO scores between 4 and 18. Exclusion criteria were patients chronically taking SSRIs, serotonin-norepinephrine reuptake inhibitors, or clomipramine, a tricyclic antidepressant.
We followed the patients in the ICU for seven days, recording information about the average daily doses of vasoactive agents, renal function, ICU length of stay, extubating time, and hospital death.
**Results:** We selected norepinephrine as a principal vasopressor agent to keep mean arterial pressure > 65 mmHg. The interim results indicated a reduction in the average dosage of norepinephrine on the 4th postoperative day in the MB group ($0.083 \pm 0.080$ vs. $0.483 \pm 0.438$ mcg/kg/min, $P = 0.022$), which is consistent with a lower level of consumption of this drug. In Fig. 1 and 2, it is possible to see the percentage of patients over time and a reduction of vasopressors in the days following the surgery.

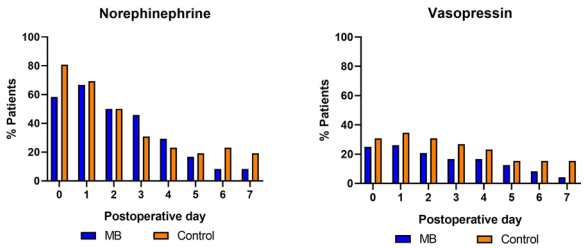

**Fig. 1 (abstract 001429)** Percentage of patients using vasopressors. MB: Methylene blue group; Control: Saline group

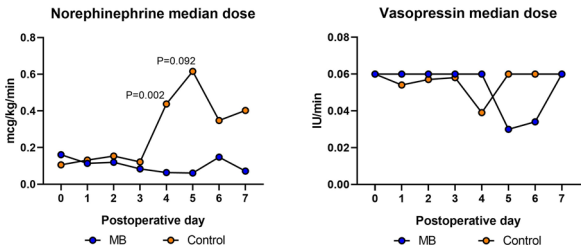

**Fig. 2 (abstract 001429)** Vasopressor drugs requirement. MB: Methylene blue group; Control: Saline group
**Conclusions:** The preliminary results show early MB in cardiac surgery patients decreased vasopressor requirements.

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001430

**Introduction:** International guidelines and weaning protocols often suggest only extubating critically ill patients receiving minimal or no vasopressors at the time of extubation. However, this practice could lead to prolonged and potentially harmful use of mechanical ventilation (MV) [1]. Retrospective analyses suggest that patients receiving low vasopressor doses might be safely extubated in a mixed medical-surgical population, but no randomized controlled trial (RCT) has been conducted [2–4]. Before conducting an RCT, that could cause patient harm, the target trial framework to analyze retrospective data can help provide insights into the causal question of whether extubating patients still receiving vasopressors at the time of extubation is safe [5,6].
**Objectives:** To investigate the average treatment effect (ATE) of a treatment strategy of extubation on vasopressors compared with a treatment strategy of discontinuing vasopressors before extubation on the risk of death by day 28 in critically ill adult medical patients.
**Methods:** An emulated target trial was conducted and included patients admitted to the ICUs of Beth Israel Deaconess Medical Center, a tertiary-level academic hospital in Boston, Massachusetts, USA. The trial included medical patients receiving controlled MV for more than 12 h, vasopressors at any point during MV, full-code status and undergoing weaning of MV before extubation, defined as having a period of assisted ventilation. The intervention strategy was defined as extubation while patients were still receiving any dose of vasopressors, whereas the control strategy was defined as vasopressors being discontinued prior to extubation (Fig. 1). The primary outcome was death by day 28 and the secondary outcome was reintubation. The primary analysis was conducted on the full population and a subgroup analysis was performed among patients receiving low-dose vasopressors ($\leq$0.1 µg/kg/min of norepinephrine-equivalent dose [7]. The causal forest, a machine learning algorithm, was used to model treatment allocation and outcomes [8]. Demographic characteristics, comorbidities, hemodynamic and respiratory parameters, vital signs, and arterial blood gas values were controlled for as confounders. The ATE of the intervention versus control strategy was estimated using the doubly robust estimator augmented inverse probability of treatment weighting (AIPW). This study was approved by the Institutional Review Board of Beth Israel Deaconess Medical Center (protocol number:2023P000649) and the requirement for informed consent was waived.
**Results:** In the present emulated trial, we included 3737 medical patients, of whom 709 (19%) received vasopressors at the time of extubation. The included patients presented a high risk of extubation failure [9], with a median age of 66 years (interquartile range [IQR]: 56–76), 44% rate of congestive heart failure, and 37% rate of chronic respiratory disease. The median last dose of vasopressor before the weaning phase of ventilation was 0.08 (IQR: 0.04–0.15) µg/kg/min for the intervention strategy and 0.03 (IQR: 0.02–0.07) µg/kg/min for the control strategy. The median duration of mechanical ventilation before the weaning phase was 36 h (IQR: 21–69). The median duration of mechanical ventilation for the weaning phase was 59 h (IQR: 20–143). In the intervention strategy, 163 (23%) patients had a total duration of MV of 7 days or more versus 1135 (37%) in the control strategy. Regarding the primary analysis, the risk of death by day 28 was higher in the intervention strategy, with an estimated excess number of deaths of 7.1 (95% Confidence Interval [CI] 2.9 to 11.3) per 100 patients compared with the control strategy (Fig. 2). The estimated number of excess reintubations was 2.3 (95% CI − 1.6 to 6.5) per 100 patients. The results were similar in the low-dose vasopressor subpopulation.
**Conclusions:** This study suggests that extubation in critically ill adult medical patients ventilated for at least 12 h and still receiving vasopressors may not be safe, also if vasopressors are administered at low doses. These findings highlight the need for further research to optimize the timing of vasopressor discontinuation at the time of extubation [10].

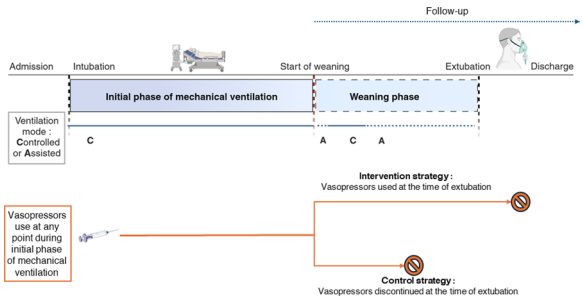

**Fig. 1 (abstract 001430)** Definition of the initial and weaning phases of mechanical ventilation and the two strategies
Each mode of ventilation was assessed and categorized as a controlled (C) mode of ventilation or an assisted (A) mode of ventilation according to the type of ventilation.
The start of the weaning phase of mechanical ventilation was defined as the time of the first period of assisted ventilation.
The initial phase of mechanical ventilation is the first continuous controlled ventilation period.
Respiratory parameters and clinical variables for confounder adjustment were extracted closest before the start of the weaning phase.

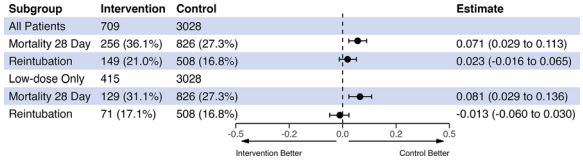

**Fig. 2 (abstract 001430)** Effect size plot of risk differences for 28-day mortality and reintubation
All patients: full population.
Low dose only: subpopulation with patients without vasopressors at the time of weaning and only low dose ($\leq$0.1 µg/kg/mn) not high dose vasopressors at the time of weaning.

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001431

**Introduction:** The concurrent management of pulmonary complications and acute brain injury (ABI) poses substantial clinical challenges. Lung protective ventilation (LPV) strategies, such as using high positive end-expiratory pressure (PEEP) and low tidal volumes, in conjunction with prone positioning, can adversely affect intracranial pressure (ICP) and cerebrovascular reactivity (PRx) (1).
**Objectives:** This study investigates the impact of PEEP on ICP and PRx in a porcine model with healthy lungs and normal ICP in the prone and supine positions.
**Methods:** Twelve anesthetized male Norwegian domestic landrace pigs, each weighing approximately 25 kg, were used to assess the effects of mechanical ventilation on cerebral hemodynamics. The pigs were randomized to start in either supine or prone positions, with the order reversed during the study. We adjusted PEEP levels every 20 min across 5, 10, 15, and 20 cmH2O (Fig. 1). ICM+® software (University of Cambridge Enterprise, Cambridge, UK) was used for data collection, signal processing, and data summaries. We correlated PEEP levels with changes in mean ICP and PRx (Pearson correlation coefficient) and evaluated the influence of positioning on the response to PEEP (linear mixed effect). We did an exploratory analysis of covariables related to the ICP increase.
**Results:** Observed increases in mean ICP at PEEP settings of 10, 15, and 20 cmH2O (over a baseline of 5) were 1.0 (±0.9), 2.0 (±1.7), and 3.1 (±1.6) mmHg, respectively. There was a positive correlation between PEEP levels and ICP changes ($r=0.25$, $p<0.001$). Positioning did not influence the response to PEEP. No significant changes in mean PRx were noted with increased PEEP. Further explorative analysis showed a significant but very weak correlation between ICP changes and both pCO2 ($r=0.08$, $p<0.05$) and lung compliance ($r=0.07$, $p<0.05$).
**Conclusions:** The results indicate that increasing PEEP levels affect ICP but does not impair cerebral autoregulation in pigs with healthy lungs and normal ICP. These findings are consistent with data from our human intervention study (BrainVent NCT03278769) (2), which also indicated slight ICP elevations with increased PEEP in brain injury patients. However, additional studies are necessary to further delineate the interaction between PEEP and ICP, particularly in the context of ARDS or intracranial hypertension.

### Respiratory trajectory subphenotypes and differences in response to PEEP/FiO2 ventilation strategy in COVID-19 ARDS

D. Filippini[1], R. Goossen[1], D. Van Meenen[1], F. Paulus[1], L. Bos[1]
[1]Intensive Care, Amsterdam UMC, locatie AMC, Amsterdam, Netherlands

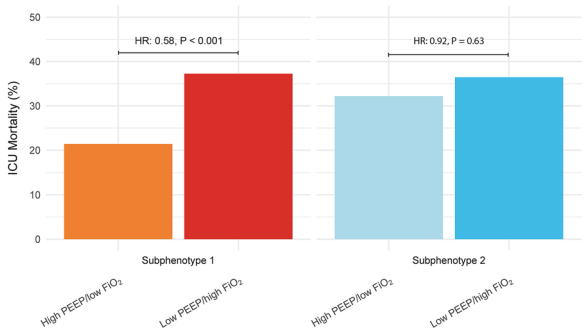
***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001433

**Introduction:** Positive end-expiratory pressure (PEEP) strategy remains a challenge in patients with acute respiratory distress syndrome (ARDS), and current guidelines make conflicting recommendations [1, 2]. Heterogeneity in the response to PEEP is an increasingly recognized factor in ARDS [3, 4]. In COVID-19-related ARDS, subphenotypes have been identified with different respiratory trajectories, although their clinical implications and their relation to the PEEP strategy remain understudied [5].
**Objectives:** We aimed to evaluate the influence of respiratory trajectory subphenotype allocation on the relationship between PEEP strategy and mortality. We hypothesized that the respiratory trajectory subphenotypes moderate the association between a high PEEP/low FiO2 ventilation strategy and mortality.
**Methods:** Retrospective analysis of a national database comprising data of invasively ventilated COVID-19 patients during the first two waves of the pandemic in the Netherlands (ClinicalTrials.gov: NCT05954351). Patients were categorized based on the ARDS Network tables into two groups; those in whom a high PEEP/low FiO2 strategy was most frequently employed in the first three days of mechanical ventilation, and those in whom it was not. To predict previously described subphenotypes, a prediction model was created using data from as early as possible up to three days of mechanical ventilation. Primary outcome was the interaction between the PEEP group and respiratory trajectory subphenotype on ICU mortality.
**Results:** Of the 1464 patients included in this analysis, 379 (25.9%) patients were categorized as high PEEP/low FiO2 and 1103 (75.3%) as low PEEP/high FiO2. A prediction model consisting of respiratory data of the first two days of ICU admission (AUROC 0.88) assigned 945 (65%) patients to respiratory trajectory subphenotype 1 and 519 (35%) patients to respiratory trajectory subphenotype 2. Subphenotype 2

was characterized by a higher mechanical power, minute volume and ventilatory ratio. The association between a high PEEP/low FiO2 ventilation strategy and ICU mortality was moderated by the respiratory trajectory subphenotype (interaction term: $P=0.033$). A high PEEP/low FiO2 ventilation was associated with lower ICU mortality only in subphenotype 1 (HR: 0.58, $P<0.001$) but not in subphenotype 2 (HR: 0.92, $P=0.63$).
**Conclusions:** High PEEP/low FiO2 ventilation was associated with better outcomes in only one of the respiratory trajectory subphenotypes, suggesting that their early identification could enhance the development of future respiratory treatment strategies.



**(abstract 001433)** Bar plot displaying mean ICU mortality in different PEEP/FiO2 strategies and assigned respiratory trajectory subphenotypes. HR = Hazard Ratio, P = P-value, ICU = Intensive Care Unit, PEEP = Positive End-Expiratory Pressure, FiO2 = Fraction of Inspired Oxygen

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001434

**Introduction:** Acute kidney injury patients on continuous renal replacement therapy (CRRT) are subjected to alterations in protein metabolism and loss of amino acids, which in turn are associated with worse clinical outcomes and mortality.
**Objectives:** The aim of this study is to determine which markers of protein and amino acid homeostasis during CRRT can be predictors of 30 days intensive care unit (ICU) mortality.
**Methods:** This was a prospective observational study on critical care patients on the 1st day of CRRT. Protein reserve was evaluated by using bioelectrical impedance derived fat-free (muscle) mass (FFMI), amino acid concentration was measured in serum by calorimetric assay (mmol/L) and loss of amino acids was calculated by measuring amino acids in effluent fluid and estimating the amount for 24 h (g/24 h). ICU mortality was defined as all cause 30 days mortality. Regression analysis was conducted to determine the predictors.
**Results:** The study was conducted between 2021 March and 2022 October. 60 high-mortality risk patients (APACHE II of $22.98 \pm 7.87$, 97% on vasopressors, 100% on mechanical ventilation) were included during the period of the study. The rate of 30 days ICU mortality was 50% ($n=30$). There was no significant difference in FFMI ($23.38 \pm 4.25$ vs $21.95 \pm 3.08$ $p=0.158$) and amino acid loss ($16.65 \pm 10.77$ vs $12.19 \pm 7.79$ $p=0.075$) between survivors and non-survivors. However, there was a difference in serum amino acid concentration ($2.40 \pm 1.06$ vs $1.87 \pm 0.90$ $p=0.040$). Regression analysis further revealed a correlation between these two markers, with a favorable effect of increasing amino acid concentration (OR = (−)0.569 CI95%: (−)0.324 to (−)0.989 $p=0.046$).
**Conclusions:** The results of the study imply an association between the lower amino acid concentration and higher ICU mortality for patients undergoing CRRT. Further investigation is needed to evaluate amino acid concentration value in clinical decision-making.

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001435

**Introduction:** Arterial pulsatile flow in the aorta is progressively dampened, transforming into continuous non-pulsatile flow at the capillary level. Nevertheless, red blood cell (RBC) velocity is dependent on systemic flow. Our hypothesis was that the respiratory changes in

the systemic flow induced by mechanical ventilation also result in variations of sublingual RBC velocity.
**Methods:** This is a sub-analysis of a previously published study (1). We studied six anesthetized and mechanically ventilated sheep. We measured sublingual RBC velocity by means of space/time diagrams (SDF-videomicroscopy and AVA 3.2 software). The respiratory variation of RBC velocity was calculated as (maximal RBC velocity-minimal RBC velocity)/ (maximal RBC velocity + minimal RBC velocity)/2) × 100. After the hemorrhagic shock, blood was retransfused in ~ 3 min. Microcirculatory measurements were performed in the same capillaries, before and at the end of retransfusion.
**Results:** The RBC velocity was increased and its respiratory variation was reduced after retransfusion (Fig. 1).
**Conclusions:** In sublingual capillaries with continuous flow, there is a variation in RBC velocity that might be dependent on the changes in systemic flow throughout the respiratory cycle. The reduced respiratory variations of RBC velocity after retransfusion probably reflects the improvement in intravascular volume and the decrease in fluid responsiveness.

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001436

**Introduction:** The incidence of pneumonia in ICU patients has been widely discussed, however, there are few studies discussing the occurrence of pneumonia in patients with chest trauma. Worldwide cohorts have evaluated age, sex, aspiration, and duration of ventilation (MV) as predictors of pneumonia occurrence, but there may be other factors affecting this relationship. On the other hand, the evaluation of the benefits of oxygenation and ventilatory mechanics of fibrobronchoscopy in patients with thoracic trauma has also not been adequately described.
**Objectives:** Main objective: To describe the patients taken to fibrobronchoscopy (FB) for any cause at San Rafael Hospital and in particular to analyze the subgroup of patients with chest trauma.
Secondary objective: to identify the potential benefit of fibrobronchoscopy in patients with blunt chest trauma.
Secondary objective: To identify the subgroup of patients who are candidates for fibrobronchoscopy according to the severity of trauma and probability of finding clots.
**Methods:** Type of study: descriptive observational, retrospective. Subjects over 18 years of age who underwent FB between 2021 and 2023 at the San Rafael Hospital in Tunja. Variables: sociodemographic, clinical, fibrobronchoscopic findings, ICU pneumonia and mortality. Statistics: quantitative variables were described by means and standard deviation, and qualitative variables by frequencies and percentages. Differences between groups were evaluated using the chi-square test for qualitative variables and for quantitative variables the Shapiro–Wilk distribution was evaluated, followed by the Student's *t*-test or Mann–Whitney *U*-test. Simple and multivariate logistic regression was performed and their respective ORS were calculated. An area under the curve analysis was performed to predict the occurrence of clots depending on the severity of the trauma.
**Results:** FB was performed in 237 patients. The mean age was 53 years and 66.24% were men, of these 28.69% ($n = 68$) had blunt chest trauma. There was an association of blunt chest trauma with the occurrence of clots [OR 7.98 (95% CI; 4.06 15.80)], atelectasis [OR 3.30 (95% CI: 1.29 10.01)], resolution of hypoxemia [OR 5.45 (95% CI; 2.71 11.41)] and prolonged ventilation [OR 2.42 (95% CI; 1.314.48)] in patients who underwent FB. Of the 237 patients taken to FB, pneumonia was diagnosed in 32.07% and this finding was associated with purulent respiratory tract secretions [OR 5.25 (95% CI; 2.79 9.94)], atelectasis [OR 3.25 (95% CI; 1.349.05)] and prolonged ventilation [OR 2.08 (95% CI; 1.15 3.76)]. Chest-specific ISS score of 9 or higher has a sensitivity of 97.87% and specificity of 42.86% (LR + 1.71, LR0.04) to predict the occurrence of clots, likewise clot removal could be a protective factor against the occurrence of pneumonia [OR 0.49 (95% CI; 0.25 0.93)] (Table 1).
**Conclusions:** FB could present a diagnostic and therapeutic tool in reducing bronchial obstruction and impact hypoxemia and prevention of pneumonia in patients with blunt chest trauma. Studies with greater statistical power and a more robust methodological design are required to estimate the impact of BF in these patients.

**Table 1 (abstract 001436)** OR of variables adjusted for the presence of chest trauma and mortality.

| Variable | Blunt chest trauma OR (CI 95%) | Death OR (CI 95%) | Pneumonia OR (CI 95%) |
|---|---|---|---|
| Age > 65 | 0.10 (0.35 – 0.26) | 4.19 (2.26 – 7.88) | 0.60 (0.31 – 1.1) |
| Men | 6.6 (2.78 – 18.06) | 0.67 (0.37 – 1.20) | 1.66 (0.87 – 3.21) |
| Blunt Chest Trauma | ( - ) | 0.29 (0.15 – 0.54) | 0.76 (0.38 – 1.46) |
| Clots // Clot removal | 7.98 (4.06 – 15.80) | 0.8 (0.45 – 1.41) | 0.49 (0.25 – 0.93) |
| Atelectasis | 3.30 (1.29 – 10.01) | 1.26 (0.63 – 2.51) | 3.25 (1.34 – 9.05) |
| Infectious pneumonitis | 1.14 (0.62 – 2.09) | 0.87 (0.49 – 1.50) | 5.25 (2.79 – 9.94) |
| Later Pneumonia | 0.76 (0.38 – 1.46) | 0.69 (0.38 – 1.24) | ( - ) |
| Hypoxemia | 0.39 (0.21 – 0.77) | 1.58 (0.84 – 2.95) | 1.5 (0.75 – 3.08) |
| Resolution of hypoxemia | 5.45 (2.71 – 11.41) | 0.36 (0.20 – 0.64) | 0.87 (0.48 – 1.56) |
| Prolonged Ventilation | 1.64 (0.88 – 3.09) | 0.64 (0.37 – 1.12) | 1.41 (0.78 – 2.57) |
| Prolonged Stay in ICU | 1.82 (0.95 – 3.56) | 0.43 (0.24 – 0.77) | 1.23 (0.67 – 2.28) |
| FB > 48 horas | 0.67 (0.36 – 1.25) | 0.74 (0.43 – 1.29) | 1.26 (0.70 – 2.26) |
| Prolonged Ventilation post-FB | 2.42 (1.31 – 4.48) | 0.47 (0.27 – 0.83) | 2.08 (1.15 – 3.76) |
| Death | 0.29 (0.15 – 0.54) | ( - ) | 0.69 (0.38 – 1.24) |

**Introduction:** Public health emergencies including the COVID-19 pandemic place significant strain on healthcare systems. The early stages of the COVID-19 pandemic resulted in significant and sustained demand for critical care services in the UK which had the potential to exceed even surge capacity [1] [2]. At such times priorities around resource allocation are questioned and reviewed. Whilst overt and explicit triage tools were never adopted in the UK, early iterations of the NICE (National Institute for Health and Care Excellence) COVID-19 rapid guideline: critical care in adults [NG159] [3], utilised the clinical frailty scale (CFS) [4] as a central tenet of a wider 'holistic assessment' of the potential benefit of critical care organ supports an individual patient may expect. Patient age was not part of this guidance. A CFS score of $\geq 5$ was narrated to be indicative of increased frailty where there may be uncertainty about the benefits of critical care organ support. Notwithstanding, this guidance encouraged patient centred, shared decision-making in fidelity with legal and professional norms [3,5].

**Objectives:** The objective of our study was to retrospectively and overtly apply the early NG159 algorithm including the CFS trigger of 5 to a cohort of patients admitted to the ICU's of three London teaching hospitals between March 2020 and February 2021 during the COVID-19 pandemic and consequently identify the potential impact of this hypothetical application.

**Methods:** A retrospective analysis of 243 patients, aged $\geq 66$ years at the time of admission to critical care units (including surge areas) in one or more of the three hospitals that form part of the Imperial College Healthcare NHS Trust, London, between March 2020 and February 2021. Three doctors independently reviewed the electronic notes (to include multidisciplinary notes) held on hospital systems of all 243 patients between April and July 2023. Working separately and blinded to each other's findings, utilising the available information at the time of ICU admission, co-morbidities and a CFS score was recorded along with an impression as to whether or not it was felt the patient would benefit from admission to critical care (triaged into or out of critical care) utilising the principles of NG159. Where a patient had a CFS recorded either on hospital or ICU admission this would be used. Otherwise, reviewers were encouraged to form a holistic view of the CFS and the potential benefit of critical care (triage status). Patients were hypothetically triaged out of ICU care if a reviewer found their CFS to be $\geq 5$ and on holistic review to 'not benefit' from critical care organ support. Patients who were triaged out by two or more reviewers had their notes reviewed by a senior doctor in confirmation of the triage status. In February 2024, all 243 patients were followed up via our local electronic portals' access to the NHS Spine to establish mortality data (at $\geq 3$ years).

**Results:** 765 patients were admitted to the ICU's during this period. 243 were aged $\geq 66$ years old and were included in the analysis. A total of 20 patients were triaged out by at least two reviewers. After consideration of the mean CFS score ($\geq 5$) and a final senior review of the patient notes and co-morbidities, a total of 12 patients were hypothetically triaged out. Of these 12 patients, 3/12 (25%) were alive for at least 3 years (as of February 2024). A total of 101 (101/243) patients were found to be alive in February 2024, thus a retrospective hypothetical application of the early NG159 guidance centred around the clinical frailty scale in those $\geq 66$ years old suggests 3/101 (2.97%) of those survivors who were alive at 3 years or more post admission may not have been admitted to critical care for organ support.

**Conclusions:** Accepting the numerous limitations of this study, we identified 3 patients who may have been denied admission to critical care had the early NICE guidance NG159 utilising the CFS been arbitarily applied to critical care admission criteria at our institutions during the COVID-19 pandemic surges. These results illustrate the potential for pitfalls and the need for caution in the arbitrary application of triage tools, particularly in situations where demand exceeds capacity and the need for collaborative clinical judgement to promote patient-centred care. It should be stated that neither the UK government or Imperial College Healthcare NHS Trust adopted any form of triage policy or tool to inform decisions on admission to critical care [6]. Furthermore whilst the early NG159 guidance appeared to primi facie promote the use of the CFS, it was caveated with the need to act in fidelity with professional judgement and the best interest of the individual.

| | Total admissions to ICU | Total admissions aged ≥66 years old |
|---|---|---|

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001438

**Introduction:** The accessibility of [18F]FDG PET/CT scans for critically ill patients has significantly improved with the introduction of long axial field of view PET/CT scanners. (1, 2) This leads to new diagnostic opportunities, and an increase of scans performed in ICU patients. (3) ICU patients emit radiation, starting directly after the administration of [18F]FDG. Since these patients require constant monitoring and frequent care, maintaining a sufficient physical distance between the staff and the patient is challenging. For the procedure a strict scan protocol was developed including staff radiation safety based on the 'as low as reasonably achievable' (ALARA) principle. This principle implies that staff radiation exposure should stay as low as possible without compromising patient care.
**Objectives:** To measure the radiation dose received by ICU personnel, during a [18F]FDG PET/CT procedure.
**Methods:** The taff radiation dose was measured during all [18F]FDG PET/CT procedures performed within our center for 1.5 years. A [18F]FDG PET/CT procedure was defined as tracer administration at the ICU department, transport to the scan facility, and the remaining decay time of [18F]FDG (4 h equalling 2 half-life times) after returning to the ICU. During the procedure, staff were advised to limit patient contact and to stay at a reasonable distance from the patient. To facilitate this, a checklist was provided encompassing transport preparation and patient care. Procedures had to be evenly divided between colleagues, only necessary staff was allowed to participate.
A electronic personal dosimeter (EPD) was provided to the participating nurse en physician to measure the received radiation doses. The EPD was carried ventral on top of the clothing at thoracic hight. The EPD was transferred between staff when shifts ended. Four hours after administration of [18F]FDG, readings were taken from the EPD.
**Results:** In total 18 [18F]FDG PET/CT procedures were performed in 16 patients. Three procedures were excluded due to incorrect use of the EPD, resulting in 15 procedures in 13 patients.
The mean (±SD) administered dose was 155 MBq [18F]FDG. The radiation dose received by nurses and physicians was, respectively, 15 µSv (SD±7) and 8 µSv (SD±4). For one physician the received dose was relatively high (20 µSv). This physician was present during the CT-scan as a precaution because of the presence of a cardiac assist device. The legal upper limit for additional radiation dose for ICU personnel in the Netherlands is 1 mSv.
**Conclusions:** The received radiation dose for ICU nurses and physicians during a [18F]FDG PET/CT procedure was acceptable and well below the recommended limits for hospital staff.

**Introduction:** Optic nerve sheath ultrasound is a bedside practice that can be used to assess increased intracranial pressure in patients with brain injuries. It is considered to be rapid, safe and easy.
**Objectives:** To identify whether ultrasonographic measurements of optic nerve sheath diameter (ONSD) could detect increased intracranial pressure and predict the prognosis of patients with acute severe brain injury on admission.
**Methods:** This was a prospective, observational study carried out between November 2023 and March 2024 in the intensive care unit (ICU) of Zaghouan's regional hospital. We included patients with severe acute brain injury, over 18 years of age, who required sedation and mechanical ventilation on admission to the ICU. A brain CT scan and an ONSUS were performed on admission in all patients.
The ONSD was measured with a high-frequency linear probe using a commercially available echocardiograph machine (Vivid T8).
Mean of measurements in both sagittal and transverse sections of each eye was used for statistical analysis. Two groups were identified and compared according to the presence or absence of intracranial hypertension on the initial brain CT scan.
**Results:** A total of 23 patients were involved. Of these patients, 20 were male, with a mean age of $44.5 \pm 13.5$ years. Mean admission severity scores of APACHE II and SAPS II were, respectively, $17.3 \pm 7.4$ and $39.4 \pm 14.6$. Acute brain injury was, respectively, secondary to traumatic lesion (14), meningoencephalitis (3), intracerebral hemorrhage (4), ischemic cerebral stroke (1) and status epilepticus (1). The mean initial Glasgow score was $7 \pm 2.4$. Seizure was noted in six patients and anisocoria in two patients.
The mean diameter of the optic nerve sheath for the total number of patients studied was 6.2 mm (range 4.6–7.8) with a standard deviation (SD) of 0.9 mm. Fourteen patients had radiological findings of intracranial hypertension on brain CT scan. When comparing the two groups, a statistically significant relationship was demonstrated between ONSD and the presence of radiological intracranial hypertension with a $p = 0.02$. Dilation of the optic nerve sheath beyond 0.59 cm accurately predicted the presence of intracranial hypertension on brain CT scans, with a sensitivity of 85% and specificity of 67% (AUC = 0.79). Neurosurgery was indicated in four cases. The median length of stay was 18 days [4–91]. Nine patients succumbed to their condition. However, no correlation was found between optic nerve sheath diameter (ONSD) and the final patient outcome.
**Conclusions:** Through the following study, we concluded that the measure of ONSD seemed to be a good approach to detect non-invasively increased intracranial hypertension in critically ill patients with acute brain injury.

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001440

**Introduction:** In 2021 an initiative was undertaken to introduce, in critical care at University Hospital Southampton (UHS), a weekly Allied-Health Professional (AHP) and pharmacist-led, multidisciplinary team (MDT) rehabilitation round for long-term Intensive Care Unit (ICU) patients; long-term defined as ICU stay $\geq 14$ days. It became apparent early in the initiation of the MDT round that vitamin D deficiency was common. Vitamin D deficiency is reported in 40–70% of patients with critical illness1. Deficiency may exist prior to admission (78% of patients present to ICU malnourished)2 or because of critically ill associated dysregulation of vitamin D metabolism. Vitamin D deficiency has been shown to increase ICU length of stay (LOS) and increase morbidity and mortality1.
**Objectives:** The aim of this study is to report the impact of the MDT ward round on vitamin D optimisation.
**Methods:** The MDT ward round was registered as a quality improvement project (QI/0242). Nutrient screening, including vitamin D was undertaken on the MDT ward round. Where deficiency was identified, evidence-based vitamin D supplementation was prescribed by the pharmacist; the presence of deficiency and intention to treat was documented in the patient's clinical notes.
**Results:** Between March 2023 to 2024, 26 patients were referred to the MDT rehabilitation ward round. Baseline vitamin D levels (Table 1) were requested, by the pharmacist, for 17 of 26 patients. Only 1 of 17 (5%) had an optimal vitamin D level at baseline, 4 were adequate, 5 were insufficient and 7 were deficient. 12 (71%) were immediately prescribed vitamin D supplementation. Doses for the identified 7 deficient patients were unless contraindicated, 300,000 units intramuscularly once only (STAT) and 10,000 units weekly (enterally/orally) maintenance. The 5 insufficient patients received replacement doses (enterally/orally) of ~ 20,000 units once weekly.
**Conclusions:** Optimisation of vitamin D (identifying deficiency and prescribing supplementation) was required in three-quarters of patients (Fig. 1) reviewed on the MDT ward round. Future work by the MDT will focus on the clinical impact and subsequent patient counselling of this important optimisation.

**Table 1 (abstract 001440)** Mortality status at least 3 years after admission to ICU demonstrating 3/12 (25%) of patients triaged out are 'alive'.

## The recruitment-to-inflation ratio reflects the impact of peep on dynamic lung strain—a CT scan study in a model of ARDS

**Correspondence:** F. Murgolo
***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001441

**Introduction:** In acute respiratory distress syndrome (ARDS), the beneficial effects of positive end-expiratory pressure (PEEP) on ventilator-induced lung injury (VILI) are proportional to the extent of dynamic lung strain reduction [1,2]. This depends on the variable recruitment produced by PEEP. Current quantification of alveolar recruitment and PEEP-induced changes in dynamic lung strain relies on computed tomography (CT), which lacks bedside accessibility. The recruitment-to-inflation ratio (R/I) is a novel tool able to predict lung recruitability at the bedside [3]. It offers valuable insights into PEEP-induced alveolar recruitment, proving its useful for setting mechanical ventilation to minimize dynamic lung strain [4].
**Objectives:** We conducted an experimental study on a high recruitable ARDS model, ventilated with two PEEP levels (low and high) in the context of a low-tidal volume lung-protective strategy, to investigate whether R/I reflects the impact of PEEP on dynamic lung strain and lung recruitability assessed through the "gold standard" CT scan method.
**Methods:** Fourteen lung-damaged pigs (lipopolysaccharide infusion) underwent CT scans at PEEPLOW (5 cmH2O) and PEEPHIGH (i.e., PEEP generating a plateau pressure of 28–30 cmH2O). Both dynamic lung strain and PEEP-induced tissue and gas recruitment were assessed through CT scan analysis: Tissue recruitment (TREC) was computed as the absolute decrease in the weight of non-aerated lung tissue between the two PEEP levels [5]. Gas recruitment (GASREC) was estimated as the amount of gas entering previously nonaerated lung units [6]. PEEP-induced dynamic lung strain variation was computed as the difference between dynamic lung strain at PEEPLOW (the ratio of tidal volume to the total end-expiratory gas volume at 5 cmH2O) and dynamic lung strain at PEEPHIGH (tidal volume divided by the sum of total end-expiratory gas volume at 5 cmH2O *plus* GASREC) [7]. Tissue recruitment and gas recruitment were normalized to the weight and gas volume of previously ventilated lung areas at PEEPLOW (normalized-TREC and normalized-GASREC). The R/I ratio was measured through a one-breath derecruitment maneuver from PEEPHIGH to PEEPLOW [3].
**Results:** The median [interquartile range] R/I ratio was 1.08 [0.88–1.82], indicating high lung recruitability (R/I > 0.5). Compared to PEEPLOW, tissue and gas recruitment at PEEPHIGH were 246 g [182–288] and 385 ml [318–668], respectively. The dynamic lung strain was 0.37 [0.29–0.44] at PEEPHIGH and 0.59 [0.46–0.80] at PEEPLOW ($p < 0.001$). R/I significantly correlated with the variation in dynamic lung strain across the two PEEP levels ($r = -0.93$; [95% CI, −0.78 to −0.98]). A strong correlation was found between R/I ratio and normalized GASREC ($r = 0.90$; [95% CI, 0.71 to 0.97]).
**Conclusions:** R/I ratio reflects the impact of PEEP on dynamic lung strain and lung recruitment, proving it is useful for setting PEEP to minimize the harmful effects of PEEP during mechanical ventilation.

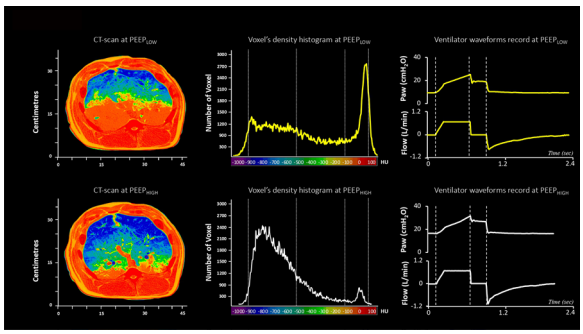

**Fig. 1 (abstract 001441)** Left and middle panels: Representative computed tomography (CT) images and corresponding voxel density histograms of a large transverse lung section acquired under two different experimental ventilation conditions at end-expiration. Each image was interpreted using the UCLA color coding table (OsiriX image processing software, http://www.osirixfoundation.com, Geneva, Switzerland). Non-aerated lung tissue, ranging from − 100 to + 100 Hounsfield Units (HU), was depicted in shades of red (from dark red to orange), poorly aerated lung tissue (between − 500 to − 100 HU) was represented in shades of green, and normally aerated lung tissue (between − 900 to − 500 HU) was coded in dark and light blue. However, hyperinflated lung tissue (ranging from − 1000 to − 900 HU), which would have been represented in purple, was not observed upon raising PEEP from PEEPLOW to PEEPHIGH. Right panel: experimental records in a representative animal showing the airflow and the opening airway pressure (Pao) traces during both experimental ventilation conditions. Dashed lines indicate the constant flow period

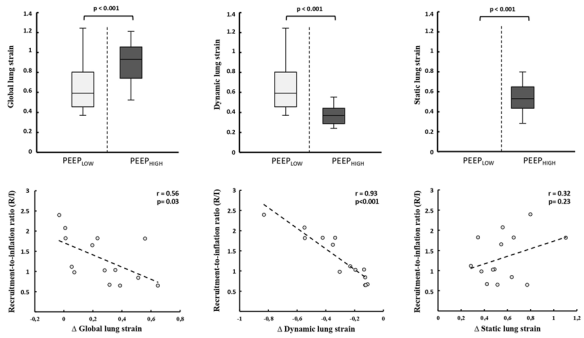

**Fig. 2 (abstract 001441)** In the upper panel, box-plot graphs represent variation in global, dynamic and static lung strain going fromPEEPLOW (*light gray*) to PEEPHIGH (*dark gray*). The lower panel depicts the correlations between the recruitment-to-inflation (R/I) ratio and the changes in global, dynamic and static lung strain going from PEEPLOW to PEEPHIGH. The dotted line represents linear regressions, and each dot represents one pig

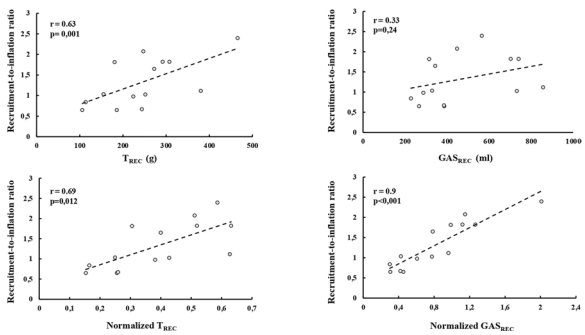

**Fig. 3 (abstract 001441)** Correlations between recruitment-to-inflation ratio (R/I) and tissue recruitment (TREC) (left upper panel), gas recruitment (GASREC) (right upper panel), normalized TREC (left lower panel) and normalized GASREC (right lower panel). Tissue and gas recruitment were assessed by the CT-scan method. Normalized TREC expresses the difference in weight of nonaerated lung tissue between PEEPLOW and PEEPHIGH divided by the total end-expiratory lung weight at PEEPLOW. Normalized GASREC expresses the PEEPHIGH-related gas volume entering the recruited lung tissue divided by the total end-expiratory gas volume at PEEPLOW. The dotted line represents linear regression, and each dot represents one pig

**Introduction:** The clinical presentation of pulmonary embolism (PE) in the emergency department is characterized by varied and nonspecific signs. Thoracic CT angiography confirms the diagnosis and rules out differential diagnoses. Rationalizing the use of this technique is essential to optimize emergency department resources. Our study aimed to investigate the relevance of requesting thoracic CT angiography in the emergency department and to determine predictive factors for alternative diagnoses.
**Objectives:** We aimed to investigate the relevance of thoracic CT angiography in the emergency department and to identify predictive factors for alternative diagnoses.
**Methods:** Prospective observational monocentric study conducted between February and September 2022. Inclusion of adult patients (age ≥ 18 years) admitted to the emergency department for suspected PE based on clinical, electrical, and biological arguments. Data on demographics, clinical, biological, and evolutionary outcomes were collected from an electronic medical record (EMR). The primary outcome was the presence of PE on CT angiography.
**Results:** We included 210 patients, with a sex ratio of 1.1. The mean age was 68 ± 16 years. The main comorbidities were hypertension (37%), diabetes (37%), and coronary artery disease (21%). The mean Geneva score was 6 ± 2.5. The probability was low in 11 patients (5.2%), intermediate in 178 (84%), and high in 18 (8.6%). D-dimer levels were negative in 13 patients (6.3%). Pulmonary embolism was found in 24.3% of patients. Alternative diagnoses found on CT angiography were: pneumonia in 20 (9.5%), pleurisy in 13 (6.1%), and COVID-19 pneumonia in 16 (7.6%). The admission rate to the intensive care unit was 15%. In-hospital mortality was 14%. The rate of discharge to home was 67%. Predictive factors for alternative diagnoses were: history of chronic respiratory failure OR = 2.11; 95% CI [1.015; 4.410]; $p = 0.046$; Troponin levels ≥ 100 ng/L; Se 70%; Sp 50%; OR 2.25; 95% CI [1.97; 2.98].
**Conclusions:** Troponin levels ≥ 100 ng/L and a history of chronic respiratory failure are predictive factors for alternative diagnoses that may lead to an unnecessary request for thoracic CT angiography in the emergency department.

**Introduction:** Acute dyspnea is a common reason for emergency department visits in patients over 85 years old. This symptom can be indicative of several potentially serious underlying pathologies. The morbidity and mortality associated with acute dyspnea are higher in the elderly due to physiological aging of the cardiorespiratory system, the multifactorial nature of dyspnea, and the frequency of associated comorbidities that can decompensate, complicating management and emphasizing the importance of identifying patients at risk of deterioration early in their admission.
**Objectives:** To identify factors associated with the occurrence of complications in elderly patients hospitalized in the emergency department for acute dyspnea.
**Methods:** Prospective, observational study conducted in the emergency department over a period of one year (2023). All patients aged 65 years and older admitted to the emergency department for acute dyspnea were included. Patients arriving in the resuscitation room in cardiorespiratory arrest were not included, and those transferred to another facility, those who refused medical advice, and those with missing data were subsequently excluded. Oral consent was obtained before data collection on the form. The primary outcome was in-hospital mortality, and secondary outcomes were admission to intensive care, intubation, and nosocomial infections.
**Results:** We included 235 patients with a mean age of $76 \pm 8$ years and a gender ratio of 1.1. The main comorbidities were hypertension in 167 patients (71%), diabetes in 99 patients (42%), heart failure in 66 (28%), and chronic obstructive pulmonary disease (COPD) in 16 (7%). The etiologies of dyspnea found in our study were acute heart failure in 103 patients (44%), community-acquired pneumonia in 74 patients (31.5%), including 12 (5%) cases of inhalation pneumonia, pulmonary embolism in 36 patients (15.3%), pleural effusion in 34 patients (14.5%), acute exacerbation of COPD in 29 patients (12%), and diabetic ketoacidosis in 26 patients (11%). Mortality was 26%. Twenty-two patients (9.4%) required orotracheal intubation, 25 (10.6%) were transferred to the intensive care unit, and 10 patients (4.3%) developed nosocomial infections. In univariate analysis, only a history of hypertension and a SOFA score $\geq 3$ were associated with mortality with respective $p$ values of 0.04 and $< 0.001$. Factors associated with transfer to the intensive care unit were the use of non-invasive ventilation (NIV) of the VS-AI-PEP type with $p < 0.001$ and a SOFA score $\geq 3$ with $p < 0.001$. Factors associated with intubation were a history of hypertension, a diagnosis of pulmonary embolism, and a SOFA score $\geq 3$ with respective $p$ values of 0.005, 0.03, and $< 0.001$. Factors associated with the occurrence of nosocomial infection were male gender ($p = 0.02$), a history of diabetes ($p = 0.05$), a history of heart failure ($p = 0.04$), a diagnosis of community-acquired pneumonia ($p = 0.02$), the use of NIV ($p = 0.004$), and a SOFA score $\geq 3$ ($p = 0.015$).
**Conclusions:** Identifying risk factors for complications in elderly patients hospitalized for acute dyspnea can improve initial management. The results of our study highlight the prognostic value of the SOFA score.

**Topic:** Acute respiratory failure and mechanical ventilation

**Introduction:** Rapid identification of microorganisms and early adaptation of anti-infectious therapy are critical in managing severe pneumonia [1].
**Objectives:** This study aimed to assess the diagnostic performance of multiplex respiratory PCR (mPCR) compared to classical microbiological culture (CMC) and to assess the mPCR's impact on early antibiotic treatment (ATB) adaptation in Moroccan ICUs.
**Methods:** Adult patients with pneumonia requiring invasive mechanical ventilation, including community-acquired pneumonia (CAP), hospital-acquired pneumonia (HAP), and ventilator-acquired pneumonia (VAP), were enrolled. Respiratory samples underwent both mPCR and CMC. The agreement between mPCR and CMC was calculated with a 95% confidence interval. Changes in empiric antibiotic therapy (ATB) induced by mPCR results were categorized as escalation, de-escalation, or adequacy. A multidisciplinary team including intensivists, infectious disease specialists, and microbiologists assessed the appropriateness of empiric ATB and the changes induced by the mPCR.
**Results:** A total of 210 patients from 12 ICUs were recruited. The median age was 50 years (range: 33–67), with 66.2% being male. The median SOFA score was 7 (range: 5–8). The distribution of pneumonia types was as follows: 31% were community-acquired pneumonia (CAP), 58% were ventilator-acquired pneumonia (VAP), and 11% were hospital-acquired pneumonia (HAP). The distribution of microorganisms detected by mPCR and CMC is displayed in Fig. 1. mPCR identified almost three times more bacterial targets than CMC, with Acinetobacter being the most identified microorganism in HAP/VAP. The percent positive agreement between mPCR and CMC was 96% (92–98%), and the percent negative agreement was 21% (15–28%). The overall agreement between the two techniques was 63% (57–67%).
mPCR results led to changes in ATB in 138 patients (65%): 25% underwent de-escalation or cessation of ATB, 23% required escalation, 18% required adequacy, and ATB was initiated in 4% of patients. The empiric ATB was deemed appropriate in 40% ($n = 84$) of patients, inappropriate in 31% ($n = 65$), and indeterminate in 9% ($n = 19$). No empiric ATB was prescribed before mPCR in 20% of patients. The appropriateness of empiric ATB significantly increased from 40% before mPCR to 66.7% after mPCR ($p < 0.001$). Post-mPCR, ATB could still be optimized in 48% of cases ($n = 102$). These potential optimizations included de-escalation or cessation of ATB ($n = 69$), escalation ($n = 30$), adequacy ($n = 18$), and initiation of ATB ($n = 3$).

**Conclusions:** This study demonstrates that in Moroccan ICUs, mPCR significantly impacts the management of patients with severe pneumonia, leading to a substantial increase in the appropriateness of empiric ATB. Further research is needed to analyse its impact on patients' outcomes, hospital costs, and antimicrobial stewardship.

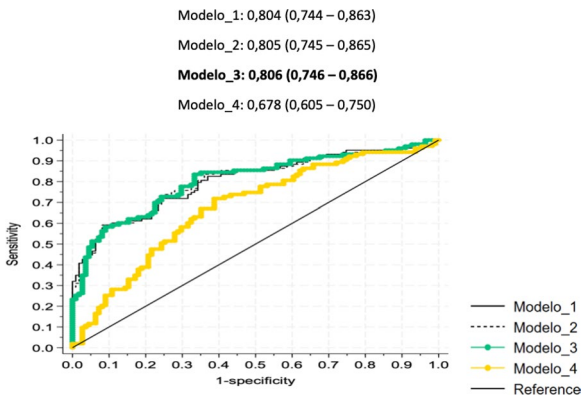
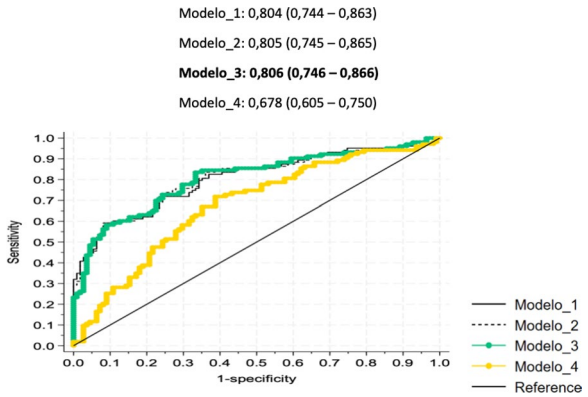
**Introduction:** The increasing impact of cancer on ICU care complicates treatment decisions, requiring shared input from oncologists and intensivists. ICU admission can optimize existing measures and align treatment with patient values.
There are mixed views on ICU mortality for cancer patients; some question its benefits due to high mortality and resource use, while others suggest it should not be generalized.
Our study focuses on predictive models for ICU admission and 3–6 month mortality in solid organ tumor patients facing acute events.
**Objectives:** The objective of the study is to identify the 3 and 6-month mortality rates of oncology patients admitted to our ICU.
**Methods:** Prospective observational study that includes patients over 18 years old with solid organ tumors experiencing an acute event and requiring evaluation by the intensive care team for ICU admission.
**Results:** The study, involving a cohort of 215 patients, found a higher ICU admission probability in men compared to women (OR = 2.62, [95% CI = 1.10–6.23]) ($p = 0.029$) and a reduced admission probability in smokers (OR = 0.27, [95% CI = 0.09–0.80]) ($p = 0.018$). The average age at 3-month mortality was 67.75 years (SD 9.77) compared to 64.95 years (SD 10.65) in survivors ($p = 0.046$).
Significantly, 23.08% ($n = 24$) of patients with heart disease died compared to 11.71% ($n = 13$) without it ($p = 0.027$). Respiratory-origin tumors showed a higher mortality probability (OR = 13.64 [95% CI = 2.75–67.63]) ($p = 0.001$). Tumors in stages II (OR = 3.13 [95% CI = 1.57–6.25]) ($p = 0.001$) and III (OR = 19.36 [95% CI = 2.15–174.35]) ($p = 0.008$) significantly correlated with 3-month mortality. Previous surgical treatment lowered the 3-month mortality probability (OR = 0.40 [95% CI = 0.18–0.92]) ($p = 0.031$), while disease progression increased it (OR = 2.12 [95% CI = 1.07–4.21]) ($p = 0.032$).
Functional assessments at admission (ECOG 2 or Karnofsky 70–50) showed higher 3-month mortality probabilities (OR = 2.42 [95% CI = 1.33–4.41]) ($p = 0.004$), increasing in ECOG 3–4 or Karnofsky 40–10 patients (OR = 8.48 [95% CI = 1.79–40.11]) ($p = 0.007$).
At 6 months, significant findings included an age difference between deceased (67.69 years, SD 9.74) and surviving patients (64.54 years, SD 10.77) ($p = 0.025$). Respiratory tumors again showed higher mortality (OR = 11.03 [95% CI = 2.35–51.89]) ($p = 0.002$), followed by digestive tumors (OR = 4.82 [95% CI = 1.13–20.51]) ($p = 0.033$). Tumors in stages II (OR = 3.42 [95% CI = 1.67–7.00]) ($p = 0.001$), III (OR = 11.97 [95% CI = 1.31–109.51]) ($p = 0.028$), and disease progression (OR = 2.29 [95% CI = 1.12–4.68]) ($p = 0.023$) correlated with higher 6-month mortality.
Functional assessments (ECOG 2 or Karnofsky 70–50) were predictive of 6-month mortality (OR = 2.95 [95% CI = 1.58–5.51]) ($p = 0.001$), increasing in ECOG 3–4 or Karnofsky 40–10 patients (OR = 14.30 [95% CI = 1.80–113.91]) ($p = 0.012$).
**Conclusions:** The model that encompasses the ECOG scale, tumor stage, vital prognosis, status of oncological disease, age, ex-smoker status, tumor extent, and renal insufficiency is the one that best predicts the probability of 3-month and 6-month mortality.



**(abstract 001448)** Predictive models of 3-month mortality in the total cohort



**(abstract 001448)** Predictive models of 6-month mortality in the total cohortT

### Acquired thrombotic thrombocytopenic purpura with severe features in the ICU: a single-center experience

A. Wahnon[1], I. Paulos Mesquita[2], J. Santos Silva[3]
[1]Serviço de Medicina Interna, Hospital de Santa Maria, Lisboa, Portugal, [2]Serviço de Hematologia e Transplantação de Medula, Hospital de Santa Maria, Lisboa, Portugal, [3]Serviço de Medicina Intensiva, Clínica Universitária de Medicina Intensiva, FMUL, Hospital de Santa Maria, Lisboa, Portugal

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001450

**Introduction:** Thrombotic thrombocytopenic purpura (TTP) is a rare hematological and critical care emergency, with a high mortality rate if left untreated. Acquired TTP (aTTP) occurs due to ADAMTS13 deficiency, and organ dysfunction arises as a consequence of widespread microvascular thrombosis. Previous studies illustrated a significant variability in TTP severity, life-supporting treatments and mortality among patients admitted to the ICU, in part due to differences in admission or plasma exchange (PEX) availability policies. We report a retrospective clinical profile analysis of 7 critically ill patients with severe TTP treated in our Intensive Care Department.
**Objectives:** Clinical review of severe features and hospital trajectories in aTTP patients admitted to the intensive care department of a tertiary university hospital in Lisbon, Portugal.
**Methods:** Clinical review of all patients admitted with newly diagnosed aTTP from 2007 to 2023, according to the intensive care department database. All identified cases were subjected to individual

medical record review regarding diagnostic workup, severity assessment, therapeutic management and clinical course.
**Results:** Among 7 patients, there were 5 females, with a median age of 51 years. All patients had microangiopathic hemolytic anemia, LDH elevation and activity level of ADAMTS13 $\leq$ 10%. Anti-ADAMTS13 autoantibodies were detected in 3 patients. No secondary causes were identified. All patients had a PLASMIC score. All patients had at least one severe neurologic manifestation and 6 had acute symptomatic seizures. The identified structural central nervous system lesions included large vessel occlusion stroke (2), isolated intraventricular hemorrhage (1), and diffuse cerebral microhemorrhages (1). Mechanical ventilation was required in 6 patients due to reduced consciousness. Acute kidney injury (AKI) was observed in 5 patients, and 2 required renal replacement therapy in the ICU. All patients with AKI recovered kidney function during the hospital stay. Cardiac involvement was documented in 2 patients (troponin elevation and pericardial effusion). There was no record of gastro-intestinal involvement or associated pregnancy. All patients were treated with PEX combined with corticosteroid immunomodulation, and in most recent years rituximab and caplacizumab were introduced as concomitant first-line treatments (4 patients, 2 with refractory disease). One patient died after the transition to end-of-life care due to catastrophic neurologic involvement and multiple comorbidities. The other 6 patients survived hospital discharge. Neurologic sequelae were present in 2 patients.
**Conclusions:** aTTP is a life-threatening disease that has faced major diagnostic and therapeutic advances over the last decade. All identified patients with this rare entity had severe neurologic manifestations and multiorgan dysfunction, emphasizing that early recognition and ICU admission can provide essential monitoring and optimized multidisciplinary care.

**Introduction:** Few data exist about the clinical features, management, complications, and outcomes of patients who require admission to the intensive care unit (ICU) for severe adverse events that frequently after Chimeric antigen receptor T-cell (CAR-T) therapy for refractory hematological malignancies.
**Objectives:** To analyze and describe the outcomes of patients receiving CART therapy and admitted to the intensive care unit.
**Methods:** This is a retrospective observational cohort study that included all consecutive adults admitted to the ICU within 3 months after CAR-T therapy from October 2019 to February 2024. Clinical syndromes were classified as cytokine-released syndrome (CRS), Immune effector cell-associated neurotoxicity syndrome (ICANS) or Haemophagocytic lymphohistiocytosis (HLH). Demographic, clinical, laboratory, management, complication, and outcome data were extracted from medical records. All patients were followed until death or hospital discharge.
**Results:** In the study period, 169 patients underwent CAR-T therapy and 41 (24.2%) required ICU admission with a median of 5 ($p$ 4–7.5) days after CAR-T infusion. Median APACHE II score was 21 ($p$ 14.5–24) 80% of the patients received Axicabtagene Ciloleucel therapy being refractory Large B-Cell Lymphoma the most frequent underlying malignancy. Forty patients were admitted due to CRS and 35 developed ICANS (80% with grade 3–4). One patient was admitted with ICANS symptoms without concomitant CRS. Haemophagocytic lymphohistiocytosis was diagnosed in 2 patients. Steroids were given to 90% of the patients including 11% who received high-dose pulse therapy. Tocilizumab was used in 33/40 (82.5%) patients, with a median of 2 [1–4] doses. Sixteen subjects (44.4% of patients with ICANS) received treatment with anakinra. Nine patients required invasive mechanical ventilation and 11 high nasal flow cannula. Sixteen patients required vasopressors and one patient was supported with continuous renal replacement therapy. Overall, 16 patients (39%) developed infections: 7 episodes of bacteremia, 5 pneumonias, 1 meningitis, and 3 invasive pulmonary aspergillosis. Six patients died during hospitalization: 5 in the period from the onset of the programme to December 2022 (5/23 = 21.7%) and 1 from 2023 to March 2024 (1/18 = 5.5%) $\chi$22.116 $p$ 0.145.
**Conclusions:** One out of every four patients receiving CAR-T therapy require ICU admission with a high incidence of ICANS. In our experience, hospital mortality is low and our data suggest an improvement in the mortality rate with the acquisition of experience in the management of these patients.

**Topic:** Haematologic-oncologic issues in the ICU

## 001452 Application of PICAT scale in patients undergoing allogeneic hematopoietic cell transplant entering the intensive care unit

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001452

**Introduction:** Application of picat scale in patients undergoing allogeneic hematopoietic cell transplant entering the intensive care unit.
**Objectives:** The PICAT scale (Prognostic Index for Intensive Care after Allogeneic Transplantation) has been proposed as an alternative to classical scores for predicting in-hospital mortality in patients undergoing allogeneic bone marrow transplantation (TAMO). The aim of this study is to compare the mortality estimated by the PICAT scale with the in-ICU mortality of TAMO patients admitted to the Intensive Care Service (ICU) of a tertiary hospital.
**Methods:** Retrospective study that included all TAMO patients admitted to the ICU over a period of 13 years. The PICAT items are time from hospital admission to ICU admission, LDH ≥ 2 upper limit of normal (ULN), bilirubin ≥ 2 mg/dL, albumin < 3 g/dL, respiratory failure as the reason for ICU admission, INR ≥ 2, myeloablative conditioning, > 60 years, Hematopoietic Cell Transplantation-specific Comorbidity Index > 2. Patients were grouped into three subgroups according to the original study: PICAT < 2; 2–4; > 4 and studied mortalities were calculated.
**Results:** During the study period, 88 patients with TAMO were admitted to the ICU. The mean age was 48 ± 14 years (60% male). The most frequent cause of hospital admission was infection (37%; $n = 33$), and in the ICU, respiratory failure (52%; $n = 47$) followed by sepsis (18%; $n = 16$). The mean time to ICU admission was 30 ± 51 days, and the mean ICU stay was 13 ± 20 days. The overall in-ICU mortality was 44% ($n = 45$).
Of the 88 TAMO patients admitted to the ICU, 29 had a PICAT score of less than 2; 41 between 2–4 and 18 > 4. The in-ICU mortality of patients according to PICAT groups was: 37.9% ($n = 11$) in PICAT < 2; 51.27% ($n = 21$) in PICAT 2–4 and 41% ($n = 8$) in PICAT > 4. These groups, according to the PICAT scale, would have corresponded to a mortality of 34%, 69%, and 91%, respectively.
**Conclusions:** In this series, in-ICU mortality, especially in groups with higher scores on the PICAT scale (PICAT 2–4 and > 4) and therefore more severe, did not correlate with the mortality estimated by this scale. Therefore, we consider that the PICAT scale is not a good predictor of mortality and does not appear to be superior to other indices more commonly used in the ICU (APACHE-II, SOFA, or SAPS3).

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001453

**Introduction:** Cardiogenic shock (CS) remains a critical condition potentially leading to multiorgan failure
associated with significant morbidity and mortality. Respiratory failure is common in the CS population representing the most common organ failure and is significantly associated with worse outcomes. Data from recent registries showed that the rate of CS patients treated with positive pressure ventilation (PPV) is up to 70%. Despite the increased use of PPV, the optimal ventilation strategy remains unclear, and hemodynamic profiles and underlying aetiologies present unique challenges for clinical decision-making.
**Objectives:** To describe the use and the relation to the outcome of different ventilation strategies in a contemporary, large, prospective registry of CS patients.
**Methods:** All patients enrolled in the AltShock-2 registry were analysed. The Altshock-2 Registry is a multi-center prospective data collection (ClinicalTrials.gov Identifier: NCT04295252).
The assessment of the need for ventilatory support and the selection of ventilatory mode [non-invasive ventilation (NIV), including continuous positive airway pressure (CPAP) and bilevel positive airway pressure, or invasive mechanical ventilation, (iMV)] were at the discretion of the treating physician. We categorized the patients into three groups according to the highest intensity of ventilatory support throughout their hospitalization: oxygen therapy (OT), NIV, and iMV.
The primary endpoint was the cumulative probability of time to all-cause death. We examined differences in aetiology, clinical and laboratory characteristics, hemodynamic, echocardiographic findings and prognostic scores on admission and at 24-h.
We prospectively assigned SCAI stages to individual patients according to the updated classification.
**Results:** Among 657 patients enrolled from March 2020 to November 30th, 2023, 198 (30.1%) received oxygen therapy (OT), 96 (14.6%) underwent non-invasive ventilation (NIV), and 363 (55.3%) underwent invasive mechanical ventilation (iMV). Patients in the iMV group were significantly younger compared to those in the NIV and OT groups (63 vs. 69 years, $p < 0.001$). There were no significant differences between the groups regarding cardiovascular risk factors. Patients with SCAI B and C were more frequently treated with OT and NIV compared to iMV (65.1% and 65.4% vs. 42.6%, respectively, $p > 0.001$), while the opposite trend was observed in SCAI D patients (12% and 12.2% vs. 30.9%, respectively, $p < 0.001$). All-cause mortality at 24 h did not differ amongst the three groups, while the 60-day mortality was significantly higher in the iMV compared to the OT and NIV groups (40.2% vs. 26% and 29.3%, $p = 0.005$), even after the exclusion of patients with cardiac arrest at presentation. In the multivariate analysis including SCAI stages, NIV was not associated with worse mortality compared to IMV (HR 1.97, 95% CI [0.85–4.56]), even in more severe SCAI stages such as D.
**Conclusions:** Compared to previous studies, we observed a rising trend in the utilization of NIV among CS patients, irrespective of the aetiology and SCAI stages. In this clinical scenario, NIV emerges as a safe option for appropriately selected patients.

*Intensive Care Medicine Experimental* 2024, **12 (suppl 1)**: 001454

**Introduction:** Rheumatologic diseases encompass a broad group of disorders, from organ-specific to systemic disorders, including systemic lupus erythematosus (SLE), rheumatoid arthritis (RA) and systemic sclerosis (SSc). In Colombia, the most prevalent connective tissue disease (CTD) is rheumatoid arthritis (1.49%), the least prevalent include SLE, Sjögren's syndrome and scleroderma (2). The course of these diseases is heterogeneous and sometimes the manifestations can be severe requiring admission to the intensive care unit (ICU). Different intrinsic and extrinsic factors of the disease make treatment a challenge (3) because ICU mortality has been reported to be between 29 and 54% (4). In Colombia, few studies provide information on patients with CTD and their behavior in the ICU (2,5); therefore, it is important to carry out studies of this nature to better characterize this patient population.
**Objectives:** To describe a cohort of patients with CTE who required admission to the ICU at a tertiary-level hospital and to identify possible variables associated with mortality.
**Methods:** Observational, descriptive study, with an analytical component in a cohort of patients with diagnoses of CTD admitted to ICU, in the period from 2018 to 2022. The Inclusion criteria were patients with admission to the ICU for any cause and with a new or previous diagnosis of CTD (SLE, RA, SSc and myopathies) and the exclusion criteria were under 18 years of age, pregnant women and medical records with incomplete data. The information was collected directly from the clinical records. Descriptive statistics were performed, describing means, modes, interquartile ranges, median, standard deviation and variance according to each type of variable, and frequency tables were used for categorical variables. After verification of normality assumptions for quantitative variables by means of the Shapiro–Wilk test, T student and Mann–Whitney tests were applied as applicable. For qualitative variables, the chi-square test was used to compare the groups for the mortality outcome.
**Results:** Of 63 patients diagnosed with CTD, mortality was 58.77%. On the other hand, 42 (66.67%) were male, and the comorbidities that showed significant differences in the mortality outcome were: systemic arterial hypertension (49.21%), chronic kidney disease (38.1%), systemic lupus erythematosus (SLE) (38.1%), antiphospholipid syndrome (APS) (19.05%), pulmonary hypertension (4.76%), The remaining general characteristics are shown in Table 1. Regarding severity criteria, when a comparison was made between living and dead patients to identify differences with respect to the Sequential Organ Failure Assessment (SOFA) score, a higher mean was found for living patients with a statistically significant difference. When comparing the groups of living and dead patients to establish the difference in the Acute Physiology and Chronic Health Disease Classification System II (APACHE II) mean, a higher score was found in the group of dead patients with a statistically significant difference. The SLEDAI 2 K score had a higher mean in the living patients without showing a statistically significant difference.
**Conclusions:** In 63 patients with CTD mortality was high. Variables associated with mortality were systemic arterial hypertension, chronic kidney disease, systemic lupus erythematosus, antiphospholipid syndrome and pulmonary hypertension. APACHE II and SOFA severity scores also showed statistically significant differences between the living and deceased groups. Prospective studies with greater statistical power and better methodological design are needed to establish which factors are related to mortality in the ICU.

**Table 1 (abstract 001454)** Baseline characteristics of CTE patients compared by mortality outcome.

| Baseline characteristics | Alive | Dead | P value |
|---|---|---|---|

**Correspondence:** A. Solé
***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001456

**Introduction:** The novel Phoenix sepsis criteria for sepsis and septic shock in children identify children with life-threatening organ dysfunction caused by a dysregulated host response to infection associated with increased risk of mortality and a subset of patients with cardiovascular dysfunction, which is associated with higher mortality. With this paradigm shift, the distances between Sepsis-3 definitions for adults and pediatric definitions are shortened.
**Objectives:** To compare the Phoenix score with the former sepsis criteria from 2005, based on systemic inflammatory response syndrome (SIRS) in terms of sepsis diagnosis and mortality prediction.
**Methods:** This is a descriptive retrospective study developed in a pediatric intensive care unit. We tested the performance of the Phoenix score on a historic database of septic patients younger than 18 years identified with the 2005 Goldstein criteria. Neonates and patients with incomplete data were excluded.
**Results:** Phoenix score could be calculated in 375 patients of the 470 that the database contained. 202 (53.9%) were male and the median age of the sample was 25.4 months (IQR: 7.6–84.1).

- 150 patients were registered as septic using 2005 criteria: these were mainly classified as non-septic using Phoenix score (121), 9 were classified as septic and 20 as septic shock. Mortality in this group was 0.6%.
- From the 29 severe sepsis detected with 2005 criteria, 13 were classified as non-septic patients, 10 as septic and 6 patients as having a septic shock.
- Most septic shock patients were also classified as patients with shock with a Phoenix score (170 of 195).

Phoenix score ≥ 2 was associated with a mortality of 4.5% and patients with septic shock (sepsis with ≥ 1 cardiovascular point), 13.3%. These results did not differ from the ones obtained when Goldstein criteria were used if we consider severe sepsis as sepsis and sepsis is considered as infection. We also did not find any differences in terms of the need for mechanical ventilation, renal replacement therapy, extracorporeal support for the length of stay in the hospital or in the pediatric intensive care unit.
**Conclusions:** 80% of the patients were classified into the same categories, using SIRS-based criteria or Phoenix score, taking into account the elimination of the term severe sepsis. Patients with incremented risk of mortality were correctly identified with both criteria.

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001457

**Introduction:** Early recognition and timely management of sepsis are crucial for improving patient outcomes. The sepsis code is a protocol designed to facilitate rapid identification and treatment of patients with suspected sepsis. This study aimed to analyze the relationship between sepsis code activation criteria and in-hospital mortality in a large cohort of patients from a university hospital in Mallorca, Spain.
**Methods:** A retrospective cohort study was conducted on 14,546 patients with sepsis code activation at a university hospital in Mallorca, Spain. The activation criteria included dichotomous variables (Y/N) for temperature > 38 °C or < 36 °C, heart rate > 100 bpm, respiratory rate > 30 breaths/min, PaCO2 < 32 mmHg, leukocytosis > 12,000/μL, leukopenia < 4,000/μL, SBP < 90 mmHg or MAP < 65 mmHg, oxemia < 90%, oliguria, decreased consciousness, creatinine rise > 1.5 × or > 0.3 from baseline, INR > 2 or platelet decrease < 100,000/μL, hyperbilirubinemia > 3.0 mg/dL, C-reactive protein (CRP) > 2 × baseline, procalcitonin > 2 × baseline, and lactate > 2 mmol/L. A propensity score was calculated to elucidate the risk associated with each activation criterion. Hierarchical clustering analysis was performed to identify patient subgroups based on activation criteria and mortality risk.
**Results:** Factors directly associated with increased in-hospital mortality included age, hypothermia, tachypnea, leukopenia, shock indicators (hypotension, hypoxia, oliguria, decreased consciousness, and elevated lactate), coagulopathy (mainly INR prolongation), and elevated procalcitonin. Fever and elevated CRP were inversely associated with mortality. Hierarchical clustering analysis revealed two main patient clusters: a younger group (mean age 45 years) with fever and

no tachypnea, and an older group (mean age 75 years) without fever but with tachypnea. These clusters demonstrated distinct mortality risk profiles.
**Conclusions:** Specific sepsis code activation criteria, such as hypothermia, tachypnea, leukopenia, shock indicators, coagulopathy, and elevated procalcitonin, were associated with increased in-hospital mortality. Conversely, fever and elevated CRP were associated with lower mortality risk. Clustering analysis identified two distinct patient subgroups with different clinical characteristics and mortality risk profiles. These findings highlight the importance of considering individual sepsis code activation criteria and patient subgroups when assessing mortality risk in patients with suspected sepsis.

**Introduction:** Antimicrobial stewardship programs (ASPs) are crucial for optimizing antibiotic use and improving patient outcomes in critical care settings. This study aimed to evaluate the impact of a clinical pharmacist-led ASP on antibiotic optimization and clinical response in a semi-intensive care unit (semi-ICU) of a high-complexity hospital.
**Methods:** A non-blinded, randomized controlled trial was conducted in the semi-ICU of a high-complexity hospital. Patients were randomized to either the intervention group, where a clinical pharmacist performed daily evaluations of antibiotic indication and optimization according to clinical guidelines and available microbiology results, or the control group, which received standard care. Demographic, clinical, and pharmacological data were collected. Therapeutic drug monitoring (TDM) interventions and clinical response at day 7 were assessed. Clinical response was defined as a decrease in fever, absence of hypothermia, > 50% decrease in C-reactive protein (CRP) or procalcitonin (PCT), PCT < 0.5, leukocyte count < 11,000, attending physician's opinion of resolution or improvement of infection symptoms, and lack of need for antibiotic escalation.
**Results:** The study enrolled 43 patients, with 24 assigned to the control group and 19 to the intervention group. The median age of the participants was 58 years (IQR 42–69), with females accounting for 55% of the study population. The median BMI was 25.7 (IQR 22.8–30.6). The most common suspected infection foci were abdominal (13/47), followed by urinary (10/47), respiratory (8/47), and other foci (16/47). In the control group, the number of patients receiving optimizable therapy decreased from 13 on day 1 to 12 on day 4. In contrast, the intervention a reduction in optimizable therapy, from 12 patients on day 1 to only 1 patient on day 4. At day 7, unfavorable responses were observed in 7 out of the 12 unoptimized patients in the control group, while none of the patients in the intervention group experienced an unfavorable response.
**Conclusions:** The implementation of a clinical pharmacist-led ASP in a semi-ICU improved antibiotic optimization and clinical response. The ASP reduced the number of patients receiving optimizable therapy and increased the proportion of patients with favorable clinical outcomes. These findings highlight the importance of pharmacist-driven interventions in critical care settings to enhance antibiotic stewardship and patient care.

### Absolute mechanical power vs mechanical power normalized by predicted body weight. ¿Which one predicts better the outcome of critically ill ventilated patients?

L. Claverias[1], N. Murillo Moreno[2], L.E. Andrade[3], M. Samper[4], O. Plans-Galván[2], A. Rodriguez[5], M. Magret[6], M. Bodí[5], S. Manrique[3]

*Intensive Care Medicine Experimental* 2024, **12 (suppl 1)**: 001460

**Introduction:** Mechanical power has been pointed out as the parameter that encloses all ventilation-induced lung injury-contributing factors. However, it is not clear its effects in critically ill ventilated patients and it is no clear either if it is necessary normalized its value by the predicted body weight or by the amount of aerated lungs.
**Objectives:** Analyze if the mechanical power normalized by the predicted body weight (noMP) is a better mortality predictor than the absolute mechanical power (AMP) in critically ill-ventilated patients.
**Methods:** Retrospective unicentric observational study in a 28-bed polyvalent ICU. All adult patients connected to invasive mechanical ventilation (IMV) > 24 h admitted to ICU from 2015 to 2022 were included. Patients ventilated at any time in pressure control mode were excluded. Demographic variables, comorbidities and severity scores were recorded at the admission time. Respiratory variables were registered continuously every two minutes during the IMV time. The median AMP was calculated as the median of all the MP values and the median norMP was calculated by dividing the AMP by the predicted body weight. Patients were divided into quartiles and a univariate and multivariate analysis were done for the AMP and norMP. The analysis were done with R software. $P$ values < 0.05 were significant.
**Results:** 2068 patients were included. The characteristics of the general population are in Table 1. The median AMP were 15 J/min (12–19) and median norMP were 0.24 (J/min/Kg) (0.19–0.29). In the univariate and multivariate mortality analysis both variables were significantly associated with an increase in mortality (Tables 2 and 3) with similar OR. Both mutivariate models have similar AUC (Figs. 1 and 2).

**Conclusions:** Higher values of AMP and norMP increase mortality rates with the same OR and AUC. Both measures of MP are useful to predict mortality.

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001461

**Introduction:** In shock, microcirculation has been proposed as a new endpoint of resuscitation (1). Despite the availability of videomicroscopy, several barriers have limited its use in clinical practice (2). Skin perfusion monitoring is increasingly used as an alternative since it can be easily performed and is widely available. Yet, the relationship between sublingual microcirculation and skin perfusion in shock is complex.
**Objectives:** To characterize the correlation of peripheral perfusion and sublingual microcirculation parameters in septic shock patients and in healthy volunteers.
**Methods:** Population: 34 healthy volunteers and 16 septic shock patients were included.
**Design**: Cross-sectional study
**Procedure:** Healthy volunteers were studied after 20 min of semirecumbent position. Septic shock patients were assessed within the first 24 h of ICU stay.
**Microcirculatory measurements:** Sublingual microcirculatory network was evaluated by means of an incident dark field illumination (IDF) imaging device. Each subject underwent 3 sublingual microcirculatory recordings. We performed a software-assisted analysis (AVA 3.2, Microvision Medical) to determine total vessel density (TVD), proportion of perfused vessels (PPV), perfused vascular density (PVD), microvascular flow index (MFI) and red blood cell velocities (RBCv). Quantitative RBCv was determined using space-time diagrams in 10 capillaries per video. Heterogeneity was shown by the Coefficient of Variation of RBCV (SD/mean).
**Skin perfusion:** Capillary refill time (CRT) was timed with a chronometer after releasing a 10-s pressure on the phalanx. Perfusion index (PI) was automatically derived from a pulse oximeter.
**Statistical analysis:** Appropriate tests were used to detect differences between healthy volunteers and septic patients. We used the Pearson correlation coefficient to assess the relationship between peripheral perfusion and microcirculation. A $P$ value $< 0.05$ was considered statistically significant.
**Results:** Healthy volunteers were 35 years old and 60% were male. Table 1 shows the clinical and epidemiologic characteristics of patients with septic shock.
*Microcirculatory variable:* Patients with septic shock showed decreased PVD, PPV, MFI, and RBC velocities along with increased heterogeneity when compared with normal volunteers (Fig. 1).
*Peripheral perfusion and microcirculatory variables:* In healthy volunteers, we did not find a correlation between CRT and RBCV ($R2 = 0.065$, $p = 0.17$), MFI ($R2 = 0$) or PVD ($R2 = 0.071$, $p = 0.11$). Conversely, in septic patients, we did find significant correlation between CRT and RBCV ($R2 = 0.44$, $p = 0.006$), MFI ($R2 = 0.36$, $p = 0.017$), but no correlation between either CRT and PVD ($R2 = 0.11$, $p = 0.2$) or CRT and PPV ($R2 = 0.20$, $p = 0.09$) (Fig. 2). Perfusion Index and CRT showed a correlation both in healthy and septic subjects ($R2 = 0.24$, $p = 0.011$, $R2 = 0.36$, $p = 0.039$, respectively.
**Conclusions:** The main finding of this study is that CRT correlated with microcirculatory parameters representative of flow but no correlation was found with parameters reflecting perfusion such as PVD and PPV.

**Introduction:** Acute respiratory distress syndrome (ARDS) is a common pathology in intensive care unit associated with a high mortality rate (40–60%) [1,2].
**Objectives:** to study characteristics of ARDS and to determine prognosis factors in burns.
**Methods:** Retrospective descriptive study was conducted in an intensive burn care department in Tunisia over 4 years (January 2018 to December 2021) including patients who developed ARDS during their ICU admission. ARDS was defined referring to the Berlin 2012 criteria.
**Results:** during the study period, 1150 patients were admitted, 360 were intubated (31%) of whom 100 developed ARDS (28%). The average age was $40 \pm 13$ years with a sex ratio of 1.8
The mean APACHE and IGSII were, respectively ($18 \pm 8{,}4$) and ($34 \pm 15{,}3$). Total body surface area burned (TBSA) was $46\% \pm 18$. The delay of occurrence of ARDS was $6 \pm 4$ days after burns. ARDS was severe in 60% of cases ($n = 60$) and moderate in 40% of cases ($n = 40$).

Causes of ARDS were: infection in 56 patients, inhalation injury in 22 patients and mixed in 22 patients. During ICU stay, patients developed complications: nosocomial infections in 71% of cases and acute kidney failure in 36% of cases. The mean duration of mechanical ventilation was 12.6 ± 5,3 days and the mean of ICU stay was 13,7 ± 5 days. Mortality was 39%. In multivariate analysis, independent mortality risk factors for ARDS were TBSA greater than 39% ($p = 0,02$), IGSII scores higher than 27 ($p < 10–3$), APACHE II higher than 14,5 ($p = 0,01$), inhalation injury ($p < 10–3$) and occurrence of shock ($p = 0,04$).
**Conclusions:** In burn patients, ARDS had a frequency of 28% and a mortality of 39%. Risk factors for mortality were: TBSA > 39%; IGSII score > 27; APACHE II > 14.5, inhalation injury and occurrence of shock.

### Impact of mechanical power in critically ill ventilated patients depending on the degree of hypoxemia

L. Claverias[1], LE. Andrade[2], A. Rodriguez[3], N. Murillo Moreno[4], O. Plans-Galván[4], M. Samper[5], M. Magret[6], M. Bodí[3], S. Manrique[2]

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001463

**Introduction:** Mechanical power has been pointed out as the parameter that encloses all ventilation-induced lung injury-contributing factors. However, studies conducted to date provide data regarding mechanical power during the early hours of mechanical ventilation that may not correspond to the real scenario.
**Objectives:** Analyzed whether the hours of invasive mechanical ventilation (IMV) with a mechanical power (MP) > 18 J/min influences the outcome of critically ill patients depending on their degree of hypoxemia.
**Methods:** Retrospective observational study conducted at a single center in Spain. Patients admitted to the intensive care unit, > o = 18 years of age, and ventilated for over 24 h were included.
We extracted the MP values throughout the entire IMV period from the clinical information system every two minutes. The sum of time values above 18J/min was calculated to obtain the value in hours. We analyzed if the number of hours the patient was under ventilation with an MP > 18J/min was associated with mortality, invasive mechanical ventilation days, and intensive care unit length of stay in the different subgroups of hypoxemia.
**Results:** During the study period, 10,874 patients were admitted to the ICU, from which 2,623 were ventilated for more than 24 h.
There were 67 (2.5%) patients in the non-hypoxemic group (SpO2/FiO2 > 355), 1259 (48%) had mild hypoxemia (SpO2/FiO2 = 355–215), 1286 (49%) moderate hypoxemia (SpO2/FiO2 = 214–90), and 11 (0.4%) severe hypoxemia (SpO2/FiO2 < 90). The comparison of the general characteristics of the different groups is shown in Table 1.
The univariate analysis showed a significant association between more hours with MP > 18 J/min and higher mortality in the non-hypoxemic, mild hypoxemic, and moderate hypoxemic groups, but no association was seen in patients with SpO2/FiO2 < 90. In the multivariate analysis, these differences only remain in mild and moderate hypoxemic groups (Tables 2 and 3). The OR in both subgroups was 1.002, which means that the probability of death increases by 0.2% for each hour with MP > 18 J/min. The contribution of MP hours > 18 J/min to IMV days was higher in severe hipoxemia (R2 = 0.83), followed by moderate hypoxemic (R2 = 0.62) and non-hypoxemic subgroups (R2 = 0.62) and, finally, folowed by mild hypoxemic patients (R2 = 0.58). The contribution of MP hours > 18 J/min on ICU LOS was approximately 50% in all subgroups (non-hypoxemic: R2 = 0.58, mild hypoxemic: R2 = 0.47, moderate hypoxemic: R2 = 0.55, severe hypoxemic: R2 = 0.51).
**Conclusions:** Continuous monitoring of MP by automated CIS analysis shows that the number of hours with MP above 18 J/min increases mortality in critically ill ventilated patients with mild to moderate hypoxemia.

### Randomized and controlled clinical trial on the effects of neuromuscular electrostimulation on exercise capacity and muscle strength in critically ill patients on invasive mechanical ventilation

J. Martínez[1], E. Gimeno[2], J. Melis Galmés[3], D. Romeu[2]
[1]Respiratory Intensive Care Unit, Physical Medicine and Rehabilitation Service, Hospital Clínic de Barcelona, Barcelona, Spain, [2]Physical Medicine and Rehabilitation Service, Hospital Clínic de Barcelona, Barcelona, Spain, [3]Intensive Care Area, Physical Medicine and Rehabilitation Service, Hospital Clínic de Barcelona, Barcelona, Spain
**Correspondence:** D. Romeu
***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001464

**Introduction:** Neuromuscular electrostimulation (NMES) is often used to prevent muscle weakness in critically ill patients admitted to the intensive care unit (ICU) with low or no level of collaboration. However, its effects are still to be elucidated.
**Objectives:** This study compared, in critically ill patients on invasive mechanical ventilation (IMV) due to respiratory pathology, the effects of NMES on exercise capacity and muscle strength at ICU and hospital discharge. In addition, time on IMV, and ICU and hospital stay were evaluated.
**Methods:** This randomized, controlled, double-blinded clinical trial was conducted at the Respiratory Intensive Care Unit of Hospital Clínic in Barcelona. Patients ($\geq$ 18 years) connected to IMV for < 72 h and expected to spend $\geq$ 24 h in IMV due to acute or chronic acute respiratory pathology were included. Both the intervention group (IG) and control group (CG) received musculoeskeletal physiotherapy but the IG additionally received NMES for 30 min/day and 5 days/week through a COMPEX 3 (Cefarcompex, Compex Médical SA, Switzerland). Exercise capacity and muscle strength were assessed by the sit-to-stand test (STS) and the medical research council (MRC) scale, respectively, at baseline (i.e.: the first day in which the patient was able to perform the test), and ICU and hospital discharge. We also evaluated time on IMV.
**Results:** A total of 8 patients in the IG (median age 64 [54–73] y.o.) and 12 patients in the CG (66 [60–74] y.o.) were included. Functional capacity through STS did not differ between CG and IG neither at ICU discharge (1.6 (2.4) vs 2.4 (4.4) repetitions; $p = 0.648$) nor at hospital discharge (3.5 (4) vs 4.6 (4.7) repetitions; $p = 0.659$). Similarly, no differences were found in MRC between groups. However, in comparison to the CG, the IG presented a shorter ICU stay (10 [8–14] vs 11 [7–23] days; $p = 0.028$) and time on IMV (6 [3–12] vs 7 [5–15] days; $p = 0.019$). Hospital stay did not differ between groups.
**Conclusions:** NMES did not provide benefits on functional capacity and muscle strength in critically ill patients invasively ventilated due to respiratory pathology. However, NMES may reduce time on IMV and ICU stay in this population of patients.

### Chrono-immunology: challenges in understanding circadian rhythm disruption in ICU

I. Camerzan[1], L. Plopa[2], E. Bahov[3], I. Pușcaș[4], C. Gutu-Bahov[2], M. Todiraș[5]

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001465

**Introduction:** The circadian clock is a sophisticated mechanism that functions to synchronize endogenous systems with the 24-h day in a wide variety of organisms. The immune system demonstrates robust circadian rhythmicity with daily variations in immune parameters, including lymphocyte proliferation, antigen presentation, and cytokine gene expression. These rhythms seem to be sensitive to perturbations in circadian homeostasis, with differential effects depending on the cell type, model system, and outcome measure.
**Objectives:** Evaluation of the degree of circadian disruption of the immune system in ICU patients and the impact on their mortality.
**Methods:** A pilot study was carried out between October 2023 and March 2024 (ICU of SCM "Sf. Treime") on a group of 50 patients. The analysis package (leukocytes, neutrophils, lymphocytes, monocytes) was evaluated in the two acrophases of the circadian rhythm day and night, analyzes were collected in the first 24 h after admission to the IT. Mean age 56.68 ± 3.45 years, $P = 0.204$. The patients were divided into two groups: group I with APACHE II score of 10–20 points Sofa 8–12 points and group II with APACHE II Score 21-28p SOFA13-18p. The clinical and laboratory data, the time spent in the ICU, the mortality rate were evaluated.
**Results:** In the patients from group I ($n = 28$) in the general analysis of the blood collected in the two acrophases, a reduced circadian rhythmicity of lymphocytes and monocytes was observed, their quantity increased by 9–14% in the evening acrophase compared to the morning acrophase. A rhythmic activity was also observed in the case of leukocytes with their increased amount in the morning acrophase by 11–13% compared to the night. In group II patients who had an APACHEII Score of 21–28 ($n = 22$), this rhythmicity was insignificant with a difference of 0.5–2% in the case of lymphocytes and 1.2–1.9% in the case of leukocytes. The lethality in group I was 7.1% ($n = 2$), in group II the lethality was 22.7% ($n = 5$).
**Conclusions:** As a result, it was observed that patients admitted to the IT in serious condition have a disrupted circadian system with an impact on their mortality. Despite active investigation of the crosstalk between the clock and the immune systems, we still understand very little about the mechanism by which clock disruption hyper-activates immunity and what effect chronic inflammation might have on the circadian machinery. The importance of chrono-immunological research goes beyond chrono-pharmacological applications, where medication can be optimized by timed drug administration. A better understanding of this area may allow preventive and improved therapeutic approaches for immunological diseases and inflammation-linked disease states including metabolic syndrome.

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001467

**Introduction:** At present, the use of adsorption membranes during cardiopulmonary bypass (CPB) could reduce cardiac surgery-associated acute kidney injury (CSA-AKI) in patients with an expected extracorporeal circulation time of more than 90 min. Furthermore, the risk of postoperative infection is high, so effective antimicrobial prophylaxis is crucial. Currently, cefuroxime is a second-generation cephalosporin administrated as antimicrobial therapy in these patients.
**Objectives:** To assess the impact of adsorption membranes connected to the cardiopulmonary bypass (CPB) circuit on plasma concentrations of cefuroxime, in the context of a randomised controlled trial (SIRAKI-02).
**Methods:** We performed a retrospective analysis of a randomised and completed clinical trial comparing the CPB connected to the oXiris membrane vs. standard CPB therapy during non-emergent cardiac surgery. For this study we selected eighteen patients that had not received any kind of ultrafiltration during cardiac surgery. The intervention group ($n = 9$) received Prismaflex eXeed II™ system with a high-adsorbent oXiris® membrane (Baxter International Inc.). Control group ($n = 9$) was subjected to the conventional procedure, which did not involve any adsorption membrane. In the intervention group, blood flow was maintained at 200–300 mL/min while the mean CPB pump flow was 4.3 L in both groups. Mean CPB time was 127 min in the intervention group and 132 min in the control group.
All patients were treated with cefuroxime in prophylaxis doses according to institutional standards. Blood samples were collected after unclamping the CPB circuit and cefuroxime concentrations in plasma were measured using ultra-high-performance liquid chromatography coupled to tandem mass spectrometry (UHPLC-MS/MS) technique.
Cut-off values of 8 mg/L from EUCAST were used as the target minimum inhibitory concentration (MIC) of cefuroxime for the most common microorganisms causing community-acquired sepsis in our

hospital: *E. coli* and *S. aureus*. Therefore, the target clinical cefuroxime concentration was four times the MIC: 32 mg/L.
Comparison between groups was assessed using the Mann–Whitney *U* test in the statistical package SPSS v25 (IBM Corp. Endicott, NY, USA).
**Results:** In both groups, cefuroxime concentrations remained above 90% of the dosing interval. Cefuroxime medians (interquartile ranges) were 42.5 (34.9–54.9) mg/L and 44.6 (32.3–57.3) mg/L for the oXiris and control groups, respectively. No statistical differences were observed between them ($p = 0.5364$).
**Conclusions:** According to the results obtained, the use of oXiris® membrane does not alter the cefuroxime concentrations in comparison with the conventional procedure. Thus, this technique could not have potential drawbacks in the context of cefuroxime administration.

### Brain not processing: how do we rationalise the use of NT-proBNP in critical care?

P. Khairnar[1], P. Featherstone[2], A. Ercole[3]
[1]Cardiothoracic ICU, Royal Papworth Hospital, Cambridge, United Kingdom, [2]Intensive Care, Addenbrooke's Hospital, Cambridge, United Kingdom, [3]Department of Medicine, University of Cambridge, Cambridge, United Kingdom

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001469

**Introduction:** BNP (B-type natriuretic peptide) and its inactive fragment NT-proBNP (N-terminal pro-B-type natriuretic peptide) are mainly secreted from the myocardium under stress. These natriuretic peptides are best in investigating isolated heart failure situations. However, they are also elevated in several other conditions; sepsis is among the most common. The cardiac involvement in sepsis is part of multiorgan dysfunction that sometimes confounds the picture of septic shock. The request for NT-proBNP attempts to detect the component of cardiogenic shock in sepsis. However, in sepsis, multiple other factors apart from cardiac involvement could independently raise the levels of natriuretic peptides, diluting its justification.1
In recent years, we have noted the increasing use of NT-proBNP in our 32-bed general ICU and 23-bed neurocritical care unit (NCCU). To rationalise this, we conducted a service evaluation of the total number of tests performed and a simultaneous literature review to understand the role of these natriuretic peptides in current practice in the non-cardiac critical care population.
**Objectives:** To determine the number of NT-proBNP tests ordered and, consequently, the cost incurred.
Undertook a literature search to establish an evidence base for using NT-proBNP in critically ill patients.
**Methods:** We conducted a service evaluation (approved by the institution) to determine the number of tests ordered from 2014 to 2023 in our 32-bed general ICU and 23-bed NCCU by ordering a data extraction from Epic electronic health record.
We assessed the cost of individual tests from the laboratory and calculated the total cost incurred.
We conducted a PubMed search using the keywords BNP or NT-ProBNP in sepsis. All three authors studied and discussed the relevant articles before reaching any conclusion.
**Results:** We noticed that NT-proBNP test requests increased yearly from 2014 to 2023. Both ICUs do not deal with a primary carer for cardiac patients.
Despite significant variation in the demographics of both ICU patients, both ICUs requested many tests, and no differentiation was noted in ordering behaviour. In some years, the requests were more from NCCUs than general ICUs (Fig. 1).
The high number of tests performed have the lowest values, but we also noticed that the tests resulted in very high values of BNP, as shown in Fig. 2.
The cost analysis shows that each test cost approximately £20, and the total cost incurred is over £100,000 in those years.
The current ESC guidelines2 recommend NT-proBNP for diagnosing and managing chronic heart failure patients. Some studies have supported using these tests to support clinical diagnosis and rule out heart failure in emergency and acute care settings. 3 However, sepsis can have independent raised levels of these peptides secondary to raised cytokines levels. 4 Other common factors associated with sepsis, like atrial fibrillation without structural heart damage, respiratory failure, renal failure, and fluid shifts, can also increase the levels.5–8 Certain conditions like obesity, flash pulmonary oedema, and pericardial tamponade may reduce the levels of natriuretic peptides. General intensive care commonly has these scenarios in their patient population. The test loses its specificity, although it maintains high sensitivity. In addition, these tests are not recommended by any intensive care society guidelines.
With this knowledge, we presented the data in a local governance meeting in March 2024, and a collective decision was made to restrict these test requests only after consultant approval to rationalise the number of tests and curb the unnecessary cost attached to them.
**Conclusions:** Excessive/irrational use of NT-proBNP in critical care settings is associated with significant hidden cost.
We will re-evaluate the use of the test in 12 months to see the effect of this project.
If we continue to see excessive/irrational use, may need an ongoing education programme for clinicians.

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001470

**Introduction:** Extracorporeal membrane oxygenation (ECMO) can be a life-saving intervention, but is still associated with high complication rates. ECMO induces systemic inflammation [1], which may activate and damage the endothelium, thereby causing edema and organ dysfunction. Previously, we showed that cardiopulmonary bypass (CPB) impairs microcirculatory perfusion [2], which was paralleled by vascular leakage and a disturbed angiopoietin/Tie2 system [3]. The angiopoietin/Tie2 system is involved in the regulation of endothelial permeability. Pharmacologically activating the endothelial Tie2 receptor with vasculotide reduced CPB-induced vascular leakage and microcirculatory perfusion disturbances [3].

**Objectives:** This study investigated whether reducing endothelial permeability by activating Tie2 using razuprotafib reduces extracorporeal circulation (ECC)-induced microvascular dysfunction.

**Methods:** Rats were subjected to 75 min of venoarterial ECC after treatment with razuprotafib ($n=11$) or placebo ($n=11$), or underwent a control procedure ($n=8$). Microcirculatory perfusion was assessed with intravital microscopy. Renal and pulmonary vascular leakage and edema were assessed by FITC-labeled dextran extravasation (70 kDa) and wet-to-dry weight ratio. Protein and mRNA analyses related to inflammation, endothelial adhesion molecule expression and the angiopoietin/Tie2 system were performed in plasma, kidney and lung tissue.

**Results:** ECC impaired microcirculatory perfusion compared to controls ($2.1\pm1.9$ vs. $13.2\pm3.2$ perfused capillaries, $p<0.0001$), which persisted one hour after stopping ECC ($5.4\pm4.6$, $p<0.05$). ECC increased vascular leakage as assessed by wet-to-dry ratio in kidneys ($4.5\pm0.2$ vs. $4.0\pm0.2$, $p<0.0001$), but not in lungs (4.8 [4.4–6.2] vs. 4.8 [4.6–5.7], $p>0.99$) compared to controls. ECC did not affect pulmonary (0.03 [0.02–0.07] vs. 0.04 [0.02–0.06] µg/mg, $p=0.99$) nor renal (0.55 [0.31–0.64] vs. 0.34 [0.15–0.63] µg/mg, $p=0.49$) FITC dextran extravasation. Compared to controls, ECC increased circulating TNF-α ($7.4\pm5.5$ vs. $0.2\pm0.1$ ng/mL, $p<0.01$), interleukin-6 ($2.6\pm1.8$ vs. $0.4\pm0.1$ ng/mL, $p<0.01$), angiopoietin-1 ($645\pm561$ vs. $25\pm16$ ng/mL, $p<0.0001$) and angiopoietin-2 ($87\pm59$ vs. $0\pm0$ ng/mL, $p<0.001$) levels, but not ICAM-1 ($34\pm8$ vs. $28\pm5$ ng/mL, $p=0.19$) levels.

Razuprotafib administration did not affect microcirculatory perfusion, wet-to-dry ratio or dextran extravasation in both organs. Interestingly, razuprotafib did not affect Tie2 mRNA, but increased VE-PTP mRNA expression by 52% in lungs ($p<0.01$), though not in kidneys, compared to placebo. Remarkably, circulating TNF-α was lower ($2.6\pm1.8$ ng/mL, $p<0.05$) following razuprotafib compared to placebo.

**Conclusions:** ECC-induced microcirculatory perfusion disturbances were paralleled by renal edema and a disturbed angiopoietin/Tie2 system. Activation of the endothelial receptor Tie2 with razuprotafib did not protect the microcirculation against ECC-induced alterations in rats.

### The development of a core outcome set for trials of airway clearance interventions in the critically ill, adult population

E. Swingwood[1], W. Stilma[2], R. Martínez Alejos[3]
[1]Adult Therapy Services, University Hospitals Bristol and Weston NHS FT, Bristol, United Kingdom, [2]Centre of Expertise Urban Vitality, Amsterdam University Applied Science, Amsterdam, Netherlands, [3]Research methodology and respiratory physiotherapy, Training Institute Physiotherapy, Montpellier, France
**Correspondence:** E. Swingwood
***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001471

**Introduction:** Airway clearance interventions are a key component of airway care, facilitating and enhancing mucociliary clearance to prevent secretion encumbrance. Patients receiving invasive mechanical ventilation have impaired cough due to the presence of an artificial airway. Sub-optimal airway clearance and resultant retained secretions predispose these patients to an increased risk of ventilator-acquired pneumonia and extubation failure. Identification of effective and safe interventions to optimise airway clearance in the critically ill is, therefore, of paramount importance. To date, studies have used various outcomes to examine the effect of airway clearance interventions. This limits the ability to compare and synthesize clinical studies. Without a core outcome set (COS), important barriers to evidence synthesis to inform clinical decision-making remain.
**Objectives:** To establish a consensus-based COS for use in future studies of airway clearance interventions in the invasively ventilated, critically ill adult population.
**Methods:** Two stages:
Item generation. A systematic search of the evidence base established a list of outcomes used in previous research examining suctioning, manual/ventilator hyperinflation, mechanical insufflation exsufflation (MI-E), nebulisation, active humidification and manual techniques. We then conducted semi-structured interviews with former patients and clinicians to identify outcomes of importance to them.
A two-round modified online Delphi study was completed, recruiting participants through professional and personal networks and social media. Outcomes for inclusion in the COS were those scored as "critical for inclusion" by $\geq$ 70% of respondents and "not important" by < 15%.
**Results:** We recruited 243 participants with international representation from 26 countries including multi-professional clinicians, researchers, industry members and ICU survivors/family. Round one was completed by 193 (78%) participants, with 136 participants completing Round two.
Item generation through systematic searches highlighted 31 items for inclusion into the delphi (round one). Interviews did not highlight any further items for inclusion. During round one, participants suggested 40 additional outcomes. Through discussion and research group consensus, due to overlap and repetition of suggested outcomes, 7 additional outcomes were agreed, totalling 38 outcomes being included in the Delphi round two.
Following two Delphi rounds, seven outcomes gained consensus. Relating to efficacy, outcomes were mechanical ventilation duration; cough strength; lung compliance; atelectasis resolution, and work of breathing; Safety outcomes included oxygen saturations and re-intubation rate.
**Conclusions:** Through a rigorous method we developed a COS for future studies of airway clearance interventions in the invasively ventilated, critically ill adult population. It is now important to gain consensus on how each of these outcomes should be measured.

### A perioperative parameter-based nomogram for predicting severe acute kidney injury in liver transplant recipients without pre-existing kidney dysfunction

Z. Li[1], X. Chen[2], C. Chen[1], Y. Gao[1], Y. Deng[3]
[1]Department of Critical Care Medicine, Renji Hospital, School of Medicine, Shanghai JiaoTong University, Shanghai, China, [2]Department of Emergency, Shanghai Pulmonary Hospital, Shanghai, China, [3]Department of Critical Care Medicine, Department of Liver Surgery, Renji Hospital, School of Medicine, Shanghai JiaoTong University, Shanghai, China

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001473

**Introduction:** Despite Liver transplantation (LT) being a lifesaving procedure for patients with end-stage liver disease, nearly half of LT recipients face the risk of developing acute kidney injury (AKI) post-surgery (1,2). In particular, severe AKI (S-AKI, AKI stage 3), leading to increased demand for renal replacement support during hospitalization and beyond, resulting in prolonged recover (3,4). For individuals without pre-existing kidney dysfunction or complications, the emergence of postoperative S-AKI presents both physically and psychologically challenges. Timely prediction of S-AKI occurrence in such patients may assist clinicians in implementing early interventions to prevent its progression, thereby potentially improving outcomes (5).
**Objectives:** This prospective cohort study aimed to develop a predictive model and construct a nomogram to forecast severe acute kidney injury (S-AKI) in liver transplantation (LT) patients without pre-existing chronic kidney disease.
**Methods:** Adults who underwent LT and were subsequently transferred to the ICU between January 2022 and June 2023 were screened. Individuals with pre-existing kidney dysfunctions were excluded. Patients were categorized based on the development of S-AKI post-LT. Factors associated with its occurrence were identified using the Least Absolute Shrinkage and Selection Operator (LASSO) method, considering preoperative, intraoperative, and postoperative factors. Machine learning techniques were employed to develop predictive models for selecting the most suitable model. The Shapley Additive Explanations method was utilized to assess the impact of each risk factor, nomograms based on these factors were developed as bedside tools for clinical application.
**Results:** Study demographic data and outcome are summarized in Table 1, among 405 patients, 44 experienced S-AKI. Identified risk factors included the MELD score, intraoperative bleeding, and postoperative levels of ALT, D-dimer, and TEG R within 24 h following LT (Table 2). Logistic regression achieved the highest AUROC of 0.885 among seven machine-learning models, indicating its suitability (Fig. 1). TEG and MELD scores had the highest weights in the Logistic regression model (Fig. 2). The nomogram, based on these factors with a point Detailed results are summarized in Fig. 1 and Table 1 at 93, demonstrated high sensitivity (70.5%) and specificity (93.4%) for predicting S-AKI post-LT (Fig. 3).
**Conclusions:** The logistic regression model, incorporating the MELD score, bleeding, ALT, D-dimer, and TEG R-value, shows promise for early prediction of S-AKI post-LT. Nomograms derived from this model offer clinical utility in various scenarios.

**Table 1 (abstract 001473)** Demographic and clinical characteristics of the study population.

### Restoring trans-laryngeal airflow after tracheostomy for critical illness: first results from the SEA CTV trial

J. McGahan[1], J. Mcnaught[2], R. Erfani[3], S. Hamdy[4], S. Wallace[5], B. Mcgrath[6]

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001474

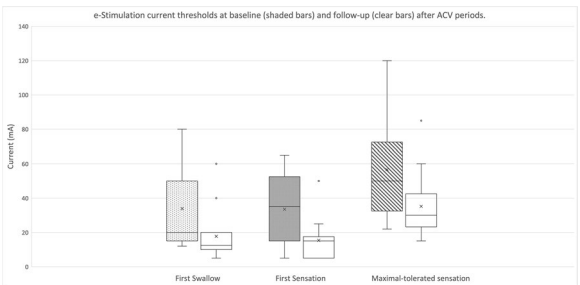
**Introduction:** Between 10 and 15% of all invasively ventilated critically ill patients require tracheostomy, typically to facilitate weaning from ventilation. [1] An inflated tracheostomy tube cuff allows positive pressure to be delivered to the lungs, but the larynx and upper airways are excluded from the flow. Retrograde gas flows can be delivered via the tracheostomy tube subglottic suction port, facilitating speech and restoring laryngeal physiological function. [2] Our medical device trial, Safe and Effective Above-Cuff Tracheostomy Vocalisation (SEA CTV) investigates the impact of above-cuff vocalisation (ACV) on laryngeal function.

**Objectives:** Measure the sensitivity of the larynx and pharynx using electrical stimulation after tracheostomy and after a period of regular ACV use.

**Methods:** Following trial registration and ethical approval (NCT04647786; IRAS 278006), 20 patients with cuff-inflated tracheostomy were recruited to the first phase of the study (focussed on assessing the safety of the SEA CTV device). Participants had a pharyngeal stimulation catheter (*Gaeltech*, Scotland) inserted nasally. A current stimulator (DS7A, *Digitimer* Ltd, UK) was triggered at 5 Hz with a 200 ms pulse width (DS2 *Digitimer* Ltd, UK). Current was slowly increased to record first and maximum-tolerated sensations, and the first observed swallow. Measurements were made at baseline and at completion of ACV, defined as: established cuff-down, ACV no longer indicated, 7-days of ACV, or death. Data distributions were summarised with mean (standard deviation) and compared using 2-tailed T-tests.

**Results:** ACV was used for a mean of 1.8 h per day, for a mean of 5.8 days. Fifteen of twenty participants had paired measurements taken (2 patients died before follow-up and 3 patients were too agitated or refused the procedure on at least one occasion). Mean (SD) currents (baseline vs follow-up, mA) were: First sensation (33.5 (20.0) vs 15.4 (12.0), $p = 0.006$); Maximal sensation (56.6 (30.9) vs (35.2 (19.1), $p = 0.032$); First swallow (33.9 (24.2) vs 17.7 (14.9), $p = 0.038$). See Fig. 1.

**Conclusions:** Stimulation currents are a surrogate of laryngeal sensitivity, which improved significantly over the course of the study intervention. Previous work has identified similar improvements using repeated pharyngeal electrical stimulation therapy, [3,4] but ours is the first study to report improvements in stimulation thresholds by restoring trans-laryngeal airflow with ACV. Future work will report laryngeal and pharyngeal functional metrics measured at nasendoscopy (FEES) and include control groups who do not receive ACV. Our results suggest that ACV may play a role in promoting early laryngeal rehabilitation after tracheostomy in critical illness.



**(abstract 001474)** e-Stimulation current thresholds at baseline (shaded bars) and follow-up (clear bars) after ACV periods. Box and whisker plots show Median (line), Mean (X), IQR and range. Dots represent outlier data

## 001476

### Diaphragmatic dysfunction in patients with prolonged mechanical ventilation

M. Valdivia Marchal[1], M.C. Bermúdez Ruiz[1], J.R. Naranjo Izurieta[1], J.F. Martínez Carmona[2], A. Rodríguez Carmona[3], J.M. Serrano Simón[1]
[1]Intensive care medicine, Reina Sofia University Hospital, Córdoba, Spain, [2]Intensive care unit, Hospital Carlos Haya, Málaga, Spain, [3]Terapia Intensiva, Hospital El Carmen, Godoy Cruz, Argentina
**Correspondence:** J.M. Serrano Simón
***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001476

**Introduction:** Diaphragm dysfunction significantly impacts clinical practice because it mainly determines the weaning outcome. The ratio of Dabdominal/Dpleural pressure can be used to assess the contribution of accessory inspiratory muscles or compensatory abdominal expiratory muscles (1); however, its relation with respiratory mechanics is necessary to determine the excessive load imposed on the inspiratory muscles.
**Objectives:** The aim is to evaluate inspiratory muscle function related to respiratory mechanics to identify the main determinants of ventilator dependence in patients with clinical signals of diaphragmatic weakness.
**Methods:** A prospective observational study was carried out at HU: R. Sofía, Córdoba, September 2023–February 2024, approved by the institutional ethics committee (Musc-Txp23). Twelve patients were included, in whom we observed clinical signs such as paradoxical (negative) oscillation of the abdominal wall, elevated hemidiaphragm on chest x-ray, and did not wean him after seven days of controlled mechanical ventilation. All patients were studied in pressure support ventilation mode.
Transdiaphragmatic pressure (Pdi) and its components, gastric pressure (Pga) and esophageal pressure (Pes), airway pressure (Paw), and flow, were recorded. Sampling 1045 Hz. For the calculations, ten respiratory cycles were averaged: Respiratory mechanics (lung and chest wall elastance, total resistances), respiration components (tidal volume, respiratory frequency, Ti/Ttot), DPgas/DPes, and DPdi/DPelast index: Pdimax, inspiratory effort partition (PTP, cmH2O*s/min), Work (WOB, J/L.
Data were analyzed by descriptive statistical methods and expressed as medians (IQR), absolute values, and percentages. The relationship between variables was carried out by linear regression.
**Results:***Characteristic of patients*: N 12. Male 9 (75%). Age 60 (56.75–64.75)y. Diagnosis: Lung transplantation 10 (83.33%); trauma 2 (16.37%). MV at study days: 15.5 (8.25–20.5). Total MV days 50 (25–79). Inspiratory support 6 (5–9.25)/PEEP 5.75 (5–6) cmH2O. Lung Elastance 15.10 (13.71–18.03) cmH2O. Total Resistances 10.44 (8.35–13.31) cmH2O/L/s. PTPelast 82.27 (58.83–151.06) cmH2O*s/min. WOB 9.13 (5.83–15.93) J/L/min. Diaphragmatic weakness causes Paralysis 8 (66.66%) and polyneuropathy 4 (33.33%). The table and figures show respiratory components and muscle function parameters.
**Conclusions:** Clinical observation is essential in detecting diaphragmatic weakness in critically ill patients. Advanced monitoring allows confirmation of the diagnosis. In the patients studied, elastic impedance and diaphragmatic paralysis were the significant determinants of the inability to overcome workload. DPgas/DPes and DPdi/DPelas index evaluate the severity and weaning outcome and could be used to establish possible therapeutic avenues.

**Introduction:** The inherent suffering of the critical disease process and the potential for severe functional impairment take part in the decision to admit to the intensive care unit (ICU). The complexity increases when involving elderly patients with chronic diseases or lower overall fitness. Nevertheless, people aged 80 years and older represent the fastest-growing subgroup in ICU admissions.
**Objectives:** The primary objective was to evaluate the proportion of very old patients ($\geq$ 80 years) admitted to an ICU and compare the baseline characteristics and acute outcomes to find predictors of hospital mortality and long-term mortality.
**Methods:** Retrospective cohort of 578 patients admitted to an ICU between January and December 2022. Patients were clustered in subgroups based on age: young (< 65 years), old (65–80 years) and very old ($\geq$ 80 years). Clinical Frailty Scale (CFS) was assessed at admission and one year after hospital discharge; score $\geq$ 4 was defined as frail.
**Results:** Median age was 61 years (IQR 50–69 years). Very old patients represented 8,5% ($n = 49$) of the admissions, with a median age of 83 years (IQR 81–85 years). 31,6% ($n = 183$) were classified as old, and 59,9% ($n = 346$) as young. Unlike the younger patients, a significantly higher proportion of very old patients were admitted after emergent surgery (32.7%, $p < 0.001$) and none had a planned admission after elective surgery. Median ICU and hospital length of stay were similar between groups, but SAPS II was higher for very old and old patients (62 vs 53 vs 42, $p < 0.001$). The proportion of frail patients in the very old group was significantly higher (83.7%, $p < 0.001$) but had no relation to ICU mortality (RR 0.84, 95%CI 0.6–1.3. $p = 0.436$). Multivariate analysis revealed that hospital mortality and one-year mortality were higher for very old patients and frail patients (RR 2.4, 95%CI 1.1–5.4, $p < 0.001$; RR 2.0, 95%CI 1.4–3.1, $p < 0.001$). In terms of organ support, those under mechanical ventilation and renal replacement therapy, but not vasopressor, also had a higher risk of mortality (RR 2.2, 95%CI 1.3–3.5, $p < 0,001$; RR 4.0, 95%CI 2.4–6.6, $p < 0.001$). 6.1% of the very old patients were discharged to nursing homes, and 5.5% and 4.0% in older and younger groups, respectively ($p < 0.001$). One year after hospital discharge, 49.4% of the survivors were classified as frail with greater risk for older patients (RR 2.9, 95%CI 1.8–4.6, $p < 0.001$).
**Conclusions:** The number of older adults requiring ICU admission has increased worldwide as the population ages. The outcome of very old patients is determined by both the severity of the acute condition and their reduced physiological reserve. Further studies may improve the capacity to differentiate the elderly that benefit from ICU admission and both age and frailty should be considered.

**Introduction:** Sleep and circadian disruptions in ICU patients are frequent and have severe consequences such as prolonged duration of mechanical ventilation and high mortality.
Studying and quantifying sleep and circadian rhythms in the ICU is challenging and limited to a few experienced teams involving a small number of patients. Large cohort studies and clinical trials have not been carried out, especially in Europe, precluding from investigating causes of sleep and circadian disruptions and slowing the development of therapeutic strategies.
Yet, significant progress has been made these last years: sleep questionnaires are now validated or very simple to use to assess patient-reported sleep experience, but are poorly correlated with polysomnography. More recently, miniaturized polysomnograph and automated sleep scoring algorithms dedicated to ICU are now available for research purposes. In addition, algorithms are being developed to monitor circadian rhythms using routinely collected clinical data from ICU patients.
**Objectives:** We wanted to investigate the number of studies on sleep and circadian rhythms performed in European countries.
**Methods:** We searched in PubMed/Medline database from 1995 to 2024 articles on sleep and circadian rhythms in ICU using the following terms: "intensive care unit" AND (sleep OR circadian rhythm) AND (Albania OR Austria OR Belgium OR Bulgaria OR Croatia OR Czech Republic OR Cyprus OR Denmark OR Estonia OR Finland OR France OR Germany OR Greece OR Hungary OR Ireland OR Italy OR Latvia OR Lithuania OR Luxembourg OR Malta OR Netherlands OR North Macedonia OR Norway OR Poland OR Portugal OR Romania OR Slovakia OR Slovenia OR Spain OR Sweden OR United Kingdom OR Turkey). We added the United Kingdom because of previous collaborations and Turkey because this country is eligible for European grants. The search was restricted to the English language and adult population. We selected only articles reporting at least one measure of sleep or one assessment of circadian rhythms in adult patients.
**Results:** From the 371 articles retrieved, 92 effectively investigated sleep or circadian rhythms in adult ICU patients. Among them, only 12 (13%) involved 2 European countries and 2 articles were multinational studies (> 2 European countries).

**Conclusions:** International collaboration in Europe for sleep and circadian rhythms studies is poor. We propose to create a **E**uropean **S**leep & **CI**rcadian **R**hythms in I**CU S**tudy group (E-SCIRCUS) gathering research teams (doctors, researchers, nurses, scientists…) in Europe interested in this topic.
The objectives of this network could be:

1. To share experience in studying sleep/circadian rhythms in ICU
2. To perform multi-center international studies, to reduce the "center effect"
3. To build a multinational database (polysomnography, sounds recordings, circadian recordings, …)
4. To apply for European grants and fund research projects of the members
5. To share and disseminate new technologies in Europe

**Topic:** Nursing care and physiotherapy

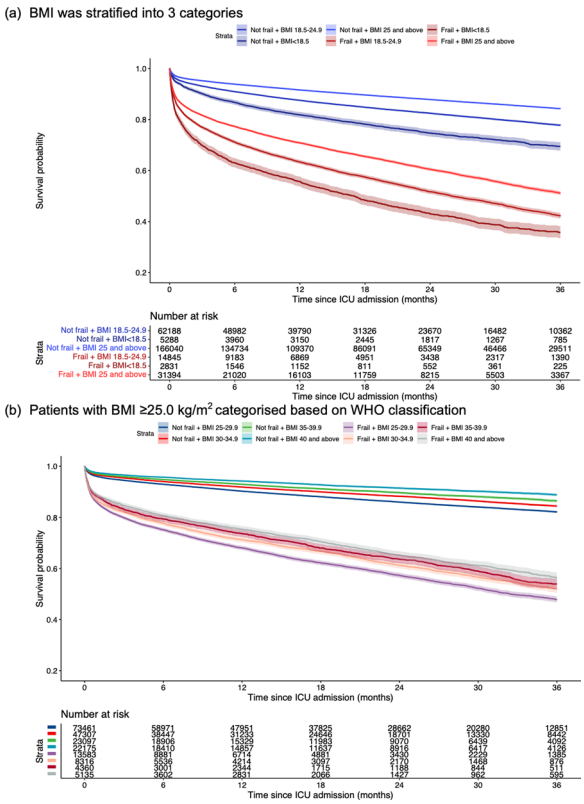
***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001481

**Introduction:** Obesity (defined as a body mass index [BMI] ≥ 30 kg/m$^2$ is increasingly prevalent [1], especially amongst individuals aged 60 years and older [1, 2]. While a BMI ≥ 25 kg/m$^2$ has been reported to be associated with frailty [3], the relationship between frailty and obesity is complex and only reported in adults in the community and admitted to the hospital. The relationship between frailty, BMI, and long-term survival has not been thoroughly investigated in patients with critical illness.
**Objectives:** We aimed to investigate the associations between frailty, BMI and long-term outcomes among patients admitted to ICU.
**Methods:** In this binational, registry-based cohort study, we included all adults admitted to Australian or New Zealand ICU's 1st January 2018 through 31st March 2022 with a documented clinical frailty scale (CFS) and a BMI. Frailty was defined as a CFS ≥ 5. The primary outcome was survival time up to three years after ICU admission, assessed using the Cox proportional hazards model along with interaction analyses between frailty, BMI and 3-year survival.
**Results:** Of the 282,586 eligible patients, 49,070 (17.4%) were frail. The patients with frailty had a lower median [IQR] BMI than those without frailty (27.4 [23.2–33.0] vs. 28.2 [24.5–33.2]). Frailty was associated with reductions in survival time (adjusted hazard ratio [aHR] = 1.67, 95%-CI: 1.62–1.73). Frailty was associated with a similar reduction in survival time amongst patients with BMI 18.5–24.9 kg/m$^2$ (reference group, 77,033 patients, aHR: 1.72, 95%-CI: 1.66–1.78) and BMI < 18.5 kg/m$^2$ (8,099 patients, HR = 1.69, 95%-CI: 1.55–1.83, pinteraction = 0.083). However, it was associated with a larger reduction in survival time in patients with BMI ≥ 25 kg/m$^2$ (197,434 patients, aHR = 1.86, 95%-CI: 1.81–1.91; pinteraction < 0.001).
**Conclusions:** An increasing BMI was associated with larger reductions in survival time in the presence of frailty. This may have implications for managing patients with concurrent obesity and frailty in the context of critical illness.



**(abstract 001481)** Kaplan–Meier survival curves of patients with and without frailty from initial admission to ICU until follow-up of up to three years. (a) The BMI was stratified into 3 categories (BMI < 18.5, 18.5–24.9 and ≥ 25.0 kg/m$^2$); and (b) BMI ≥ 25.0 kg/m$^2$ is categorised based on WHO classification (BMI 25.0–29.9, 30.0–34.9, 35.0–39.9, ≥ 40 kg/m$^2$)

**Introduction:** Bed block problems including delayed and after-hours discharge have been a consistent, major issue especially for Australian regional ICUs1. Research evidence has shown that discharge delay and after-hours discharge are associated with increased ICU and hospital length of stay leading to worsened patient outcomes and increased healthcare costs 2,3. There is limited in-depth understanding in the literature on the actual discharge process.
**Objectives:** This study aimed to understand the barrier and facilitators to the ICU patient discharge process in adult ICUs.
**Methods:** This was a qualitative exploratory multisite study. It was conducted in three regional adult ICUs in Queensland. We used fieldnote taking, interviews with staff and consumers and document analysis as data collection techniques. Content analysis was conducted following a deductive Structure, Process and Outcomes framework and then an inductive process using the Theoretical Domains Framework.
**Results:** We observed 69 discharges across three sites and conducted 76 interviews with 59 staff and 17 consumers. Qualitative data analysis revealed barriers to discharge including ineffective communication and coordination, within and across teams and departments; uncertainty and inconsistency in discharge decision making and lack of patient/family involvement in discharge decision making especially on the timing of discharge. In addition, ICU has been given low priority when allocating ward bed with patients being discharged based on ICU bed demands rather than patient discharge criteria. Facilitators included clarity on professional roles in ICU discharge; effective communication within the ICU team and context-specific strategies to support the discharge process.
**Conclusions:** The findings provide an in-depth understanding of the barriers and facilitators to the ICU discharge process which will inform future targeted interventions to address the bed block issue.

**Introduction:** Acute respiratory distress syndrome (ARDS) can be clinically subgrouped into phenotypes based on the distribution of infiltrates and hyperinflated areas seen on computed tomography (CT). An individualized ventilation treatment strategy tailored towards the specific phenotype (focal or diffuse distribution pattern) seems to be beneficial, and treatment approaches based on an inaccurate CT assessment have been shown to increase mortality [1]. Current methods of ARDS characterization on CT are solely subjective, and an objective method of measurement might increase the accuracy of the assessment.
**Objectives:** The objective of this study was to investigate and characterize the spatial distribution of pulmonary infiltrates and hyperinflation on CT in patients with diffuse ARDS. The study also aimed to create a CT-based score (the Focal-CT score) as a complementary analysis method in the process of grading focal injury determining ARDS phenotype.
**Methods:** CT scan images of mechanically ventilated patients with SARS-Covid-19 and moderate to severe ARDS, admitted to the intensive care unit at Uppsala University Hospital, Sweden, were analyzed retrospectively. The distributions of Hounsfield units (HU) (measured as a percentage of the total amount of voxels) were depicted in histograms for nine equally sized regions of the lungs. The overlap of the area under the curve (AUC) between the apical non-dependent and diaphragmatic dependent areas was used to derive a score of HU distribution. The Focal CT score ranged between 0 and 200, calculated as the absolute value of the difference in AUC between these regions' histograms. A Focal CT-score of 0, deriving from a complete overlapping of the two HU distribution profiles, was interpreted as diffuse ARDS. A Focal CT score of 200, deriving from a complete separation of the two profiles, was interpreted as focal ARDS [2] (see Figure). For the purpose of validation, the ARDS phenotypes were also characterized by visual assessment of the CT scan images by three senior ICU physicians, blinded towards each other's assessments. Clinical data from medical records were also collected from the ICU stay.
**Results:** Thirty-six patients (six women; median age 65 years) were included in the study with a median duration of 4.5 days (IQR 1–8.5) between the dates of ICU admission and CT scanning. All study objects' chest CT images were characterized visually and diagnosed as diffuse ARDS. The mean PEEP set during the CT scan was 13.0 cmH2O (SD ± 3.3) and the median duration of mechanical ventilation was 9 days (IQR 5–18). The mean Focal CT Score was 95.5 ± 42.8, 95% CI, 81.0–110.0 (see Figure).
**Conclusions:** Patients subjectively categorized as diffuse ARDS display morphological changes on CT with a varying degree of focality. Diffuse and focal ARDS are not univocally discernible. Future studies with larger cohorts of patients of various ARDS etiologies are needed to examine diagnostic accuracy and validate this score as a clinical tool.

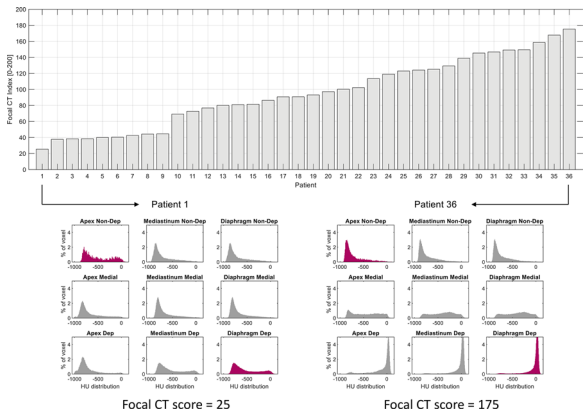

**Fig. (abstract 001484)** Focal CT score in the patients cohort. Above: Histogram reporting the Focal CT score for the 36 patients included in the analysis. Below: HU distribution for the nine defined tredimensional regions of interest (ROI, i.e., Apex non-dependent, Apex medial, Apex Dependent, Mediastinum non-dependent, Mediastinum medial, Mediastinum Dependent, Diaphragm non-dependent, Diaphragm medial, Diaphragm dependent). HU-distribution histograms

characterzed by 5 HU bins and y-axis reporting the percentage of a total voxel in that ROI. The Focal CT score is calculated as the absolute value of the difference between the areas under the curve for the HU-distribution of the Apex non-dependent ROI and and the Diaphragm dependent ROI. The two patients with the extreme values of Focal CT score are reported

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001485

**Introduction:** COVID-19 is an inherently prothrombotic condition, and a high proportion of COVID-19 patients develop pulmonary embolism. Studies have consistently observed that a significant proportion of patients with respiratory distress syndrome (ARDS) caused by COVID-19 exhibit right ventricular (RV) dilation, RV dysfunction, or acute cor pulmonale. However, the true role of thromboembolism in right ventricular function in this patient cohort is not clear.

**Objectives:** our aim was to assess the impact on right ventricular function following pulmonary embolism in mechanically ventilated patients with COVID-19.

**Methods:** Post hoc analysis of prospective, multicenter study in four university-affiliated hospitals in Chile. Consecutive patients with COVID-19 ARDS requiring mechanical ventilation admitted between April and July 2020 were included. We performed transthoracic echocardiography within 24 h of CT angiography due to clinical suspicion of pulmonary embolism.

**Results:** 175 mechanically ventilated patients were screamed, in 140 patients first CCE was performed within 24 h of ICU admission and in 86 patients CT angiography was performed within 24 h, and in seven patients a CT angiography was performed during the first week. A total of 93 patients (age 57 ± 12 yr, 29 female patients (21%) were included in the study. Severity of disease on admission was APACHE II 15 [IQR 11–21] and SOFA 7 [IQR 5–9], and ICU mortality was 31 (33%). Twenty-six patients (28%) exhibited PE (20 patients had segmental or subsegmental thromboembolism and six patients exhibited lobar pulmonary embolism), and none patients showed massive PE. Forty-two patients (45%) had RV dilation, out of whom fifteen patients (36%) exhibited PE. Twenty patients exhibited ACP out of whom nine (45%) showed PE (a comprehensive comparison between patients with and without ACP was shown in Table 1).

**Conclusions:** Pulmonary embolism was not related to worse right ventricular performance, pulmonary mechanics, hemodynamic instability, or ICU mortality. Nonetheless, the presence of pulmonary embolism was related to acute cor pulmonale in 45% of the cases.

**Table 1 (abstract 001485)** Hemodynamic and echocardiographic parameters between patients with and without PE.

Continuous data were expressed as median [25th–75th percentiles]. Categorical variables expressed as number (percentage). Five patients with normal right ventricle (RV) function were excluded from the analysis due to poor delimitation of RV free wall. SBP = systolic blood pressure; DBP = diastolic blood pressure; MAP = median arterial pressure; NE = norepinephrine; HR = heart rate; CVP = central venous pressure; LVEDV = left ventricular end diastolic volume; LVESV = left ventricular end systolic volume; MAPSE = mitral annular plane systolic excursion; LVOT = left ventricular outflow tract; VTI= velocity time integral; TAPSE = tricuspid annular plane systolic excursion; TDI = tissue Doppler imaging; RVEDA/LVEDA ratio = right ventricle end diastolic area/left ventricle end diastolic area ratio; E/A ratio = E wave/A wave ratio; E/e' ratio = E wave/tissue Doppler image e' wave ratio; IVC = inferior vena cava.

**Introduction:** Despite lung protective ventilation strategies, the regional heterogeneity of lung mechanics characterizing acute respiratory distress syndrome (ARDS) determines the unpredictable regional

distribution of gas, causing hyperinflation and lung collapse and, as such, ventilator-induced lung injury and increased mortality [1]. Positive end-expiratory pressure (PEEP), as well as fluid status and lung oedema, can further influence gas distribution within the lung. Computed tomography (CT) is a reliable way to investigate regional inflation and estimate hyperinflation and lung collapse.

**Objectives:** Using lung CT analysis, we investigated regional gas distribution, comparing Hounsfield unit (HU) distribution profiles of dependent and non-dependent lung regions. The study also aimed to investigate the relationship between the heterogeneity of gas distribution and PEEP, fluid status and lung oedema.

**Methods:** Mechanically ventilated patients with moderate to severe COVID-19 ARDS, admitted to the intensive care unit (ICU) at Uppsala University Hospital, Sweden, underwent lung CT during their ICU stay, and were included in the study. The HU profiles, measured as a percentage of the total amount of voxels, were obtained for three equally sized regions of the lungs (i.e., non-dependent, mediastinal, dependent). To quantify the regional distribution of hyperinflation and lung collapse, the absolute difference between the HU profile for the non-dependent and the dependent areas was computed for each patient. This difference ranged between 0 and 200; where 0 indicated a complete overlapping and 200 a complete separation of the two HU profiles. Lung weight, a surrogate for lung oedema, was calculated from the sequence of CT scans, following the interpolation method [2]. Clinical data were collected from medical records. Data were reported as mean (± standard deviation). Correlations were sought using Spearman rank correlation. F-test statistics ($\alpha = 0.05$) were used for the linear regression analysis.

**Results:** Thirty-six patients were included in the study. PEEP set during the CT scan was 13 cmH2O (± 3) and the mean cumulative fluid balance was 3285 ml (± 2705). The difference between HU profiles was 76.9 ± 36.9, 95% CI:64.4–89.3 (Fig. 1a). The estimated lung weight was 1683 g (± 815). Changes in lung weight (rho = 0.66, $p < 0.001$; R2 0.31, $p < 0.001$), but not in set PEEP (rho = 0.17, $p = 0.33$; R2 0.05, $p = 0.20$) and cumulative fluid status (rho = 0.12, $p = 0.51$; R2 0.001, $p = 0.82$), were significantly correlated with the difference in HU-profiles between dependent and non-dependent regions (Fig. 1b).

**Conclusions:** This study showed variable hyperinflation and lung collapse within the lung parenchyma. Lung oedema, but not fluid status or set PEEP, was significantly associated with the difference in gas distribution between dependent and non-dependent lung regions. Larger studies, including different ARDS aetiologies, are needed to confirm these findings and investigate their impact on clinical outcomes.

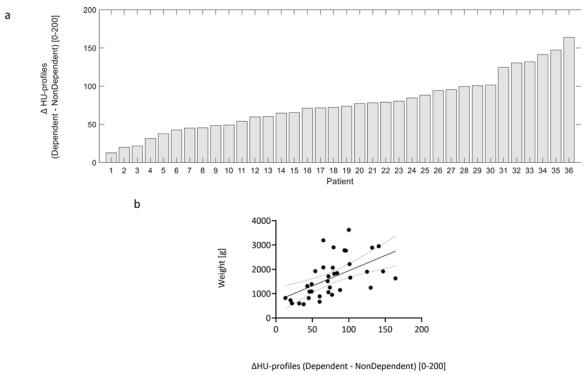

**Fig. 1 (abstract 001486)** A) Absolute differences between HU profiles between dependent and non-dependent lung regions (Δ HU profiles (Dep- NonDep)). Value reported for each patient. B) Linear regression between the Δ HU profiles (Dep- NonDep) and lung weight [g]

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001487

**Introduction:** Many drugs that are cleared by the kidneys require dose adjustments to avoid the risk of adverse drug reactions. It is widely accepted that in renal impairment, drug doses can be adjusted proportional to the estimated glomerular filtration rate (eGFR), which is based on the plasma creatinine. The underlying theory supporting this method is the intact nephron hypothesis (INH). According to the INH, the total renal drug clearance is considered linearly related to the glomerular filtration rate (GFR), even when the drug is (also) cleared by tubular secretion. Although milrinone is a drug that is known to

undergo tubular secretion, details of its clearance in ICU patients are unknown.
**Objectives:** Examine renal milrinone clearance in relation to measured creatinine clearance (mCC) in ICU patients.
**Methods:** This observational study used left-over plasma and 24 h urine samples to measure serial milrinone and creatinine levels in ICU patients receiving a continuous milrinone infusion. The samples were only analyzed when no renal replacement therapy was given. Lithium heparin plasma and urine samples were analyzed by liquid chromatography-tandem mass spectrometry (LC–MS/MS). Renal milrinone clearance was determined as:
694· (milrinone excretion in mg/d) / (plasma milrinone in µg/L).
The measured creatinine clearance (mCC) was determined as:
694· (creatinine excretion in mmol/d)/plasma creatinine in µmol/L).
The renal milrinone clearance and mCC were compared with linear regression analysis.
**Results:** Eighteen patients were included (13 men and 5 women), from whom 163 plasma samples and 40 24 h urine samples of 24 h urine were collected. The milrinone administration rates ranged from 0.50 to 2.88 mg/h (0.09 to 1.00 µg/kg/min), with plasma concentrations from 60 to 475 µg/L. Renal milrinone clearance varied from 2 to 387 mL/min and mCC varied from 2 to 121 mL/min. The relationship between the milrinone renal clearance and mCC was linear ($R^2 = 0.79$; $P < 0.001$), with a ratio of 2.42 (95% CI 2.23 to 2.61).
**Conclusions:** In ICU patients, the renal milrinone clearance is more than double the measured creatinine clearance. With a linear relation across a range of clearances, renal milrinone handling follows the intact nephron hypothesis.
Thus linear milrinone dose adjustments based on the mCC in critically ill patients with renal impairment seem justified.

*Intensive Care Medicine Experimental* 2024, **12 (suppl 1)**: 001488

**Introduction:** Quality of life (QoL) is a subjective perception of a person's well-being level influenced by sociocultural structures. Indicators of high QoL are a person's ability to carry out daily activities, maintain a good level of mobility, functional independence from others, self-service, social contacts, emotional stability, and no feeling of pain or other symptoms of discomfort [1]. Both preoperatively and postoperatively, QoL plays a vital role in the outcome after cardiac surgery and is affected by preoperative, intraoperative, and postoperative factors [2]. Patients often experience pain, discomfort, muscle weakness, reduced function, symptoms of depression, and an inability to return to their preoperative levels of function. These symptoms significantly diminish their level of QoL.
**Objectives:** This study investigated the QoL of patients who underwent cardiac surgery and the correlation of QoL with gender and sex.
**Methods:** This observational study included 578 consecutive patients who underwent cardiac surgery (CABG, surgical valve replacement/reconstruction, other heart surgery) and were hospitalized in the Cardiac Surgery ICU. Three months after their discharge from the hospital, the QoL was assessed with the EuroQol 5-Dimension 5-level (EQ-5D 5L) health status questionnaire.
**Results:** Of the total, 408 patients aged 70 (62–75) years were evaluated. The respondents' rating of their 'health today' as captured with the Visual Analogue Scale (EQ-VAS) score was 80 (70–90) and negatively correlated to age, $r\ (406) = -0.115$, $p = 0.02$). According to the EQ-5D-5L index value, the rates of self-reported problems (slight, moderate, severe, or extreme) were 46.6% ($N = 190$) for mobility, 41.2% ($N = 168$) for pain/discomfort, 38.5% ($N = 157$) for anxiety/depression, 19.9% ($N = 81$) for usual activities and 6.9% ($N = 28$) for self-care. Women reported higher rates of mobility problems (slight, moderate, severe, or extreme) compared to men [67.1% ($N = 57$) vs. 41.2% ($N = 157$), $\chi 2 = 23.924$, $df = 4$, $sig < 0.001$]. Patients over 65 years old experienced more difficulties (slight, moderate, severe, or extreme problems) with usual activities compared to participants $\leq 65$ years old [23.9% ($N = 65$) vs. 11.8% ($N = 16$), $\chi 2 = 9.873$, $df = 4$, $sig = 0.043$].
**Conclusions:** Patients report a good quality of life in the short-term period after cardiac surgery. Gender and age affect the postoperative quality of life, with women and older patients experiencing deterioration in mobility and ability to perform usual activities, respectively.

*Intensive Care Medicine Experimental* 2024, **12 (suppl 1)**: 001489

**Introduction:** Acidemia is a common clinical finding in critically ill patients admitted to the intensive care unit (ICU). This metabolic disturbance can result from a variety of etiologies. Although acidemia has long been recognized as a marker of systemic disease, its prognostic importance in predicting patient outcomes, particularly mortality, remains an area of active research.
**Objectives:** The aim of this study is to investigate the association between acidemia and mortality among patients admitted to the ICU, to determine whether the presence of acidemia on admission is predictive of a higher risk of mortality.
**Methods:** Retrospective observational study to explore the relationship between acidemia and various clinical variables in patients admitted to an ICU in 2023. Two groups were defined: group 1 (G1) with a pH level $< 7.35$, and group 2 (G2) with a pH level $\geq 7.35$. Clinical data included demographic information, ICU stay duration, mortality rates, need for invasive mechanical ventilation (IMV), admission reason, arterial blood gas parameters (pH, pCO2, HCO3), laboratory values (urea, creatinine), and requirement for renal replacement therapy (RRT). Statistical significance was defined as $p < 0.05$.
**Results:** The study involved 477 patients, with G1 ($n = 119$) and G2 ($n = 358$). G1 had an average age of 67.6 years, 33.6% of women and G2 64.8 years with 34.6% of women. Age and gender differences were not statistically significant. G1 had a slightly higher proportion admitted for medical reasons (74.8%) compared to G2 (66.2%), though not

statistically significant ($p = 0.081$). Patients in G1 had higher severity criteria on admission than those in G2, with statistically significant differences in several parameters: a higher percentage of G1 patients (60%) were admitted to level 3 of care compared to G2 (42.7%) ($p < 0.001$); ICU mortality was significantly higher in G1 (31.1%) compared to G2 (17.6%) ($p = 0.002$). Similarly, hospital mortality after ICU discharge was also significantly higher in G1 (38.6%) compared to G2 (25.4%) ($p = 0.006$); G1 patients had a significantly lower mean pH (7.19 vs. 7.42, $p < 0.001$) and higher mean pCO2 (43.8 vs. 38.6 mmHg, $p < 0.001$) compared to G2. In addition, the mean HCO3- level was significantly lower in G1 (18.1 vs. 24.8 mEq/L, $p < 0.001$). The average concentrations of creatinine (mg/dL) (2.6 vs. 1.6, $p < 0.001$) and urea (mg/dL) (100.9 vs. 70.6, $p < 0.001$) were significantly higher in G1 compared to G2. A higher percentage of patients in G1 required IMV (60.5% vs. 31%, $p < 0.001$) and RRT (31.1% vs. 7.2%, $p < 0.001$) compared to G2.

**Conclusions:** These results suggest that patients with acidemia on admission to the ICU had a more severe clinical profile and worse outcomes compared to those without acidemia. The differences observed underline the prognostic significance of acidemia in critically ill patients and highlight the importance of early recognition and appropriate management of this metabolic disorder.

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001490

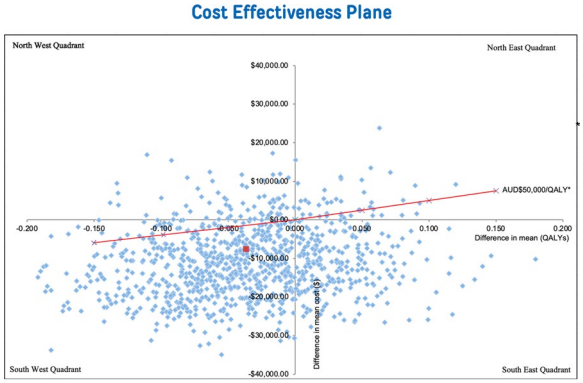
**Introduction:** Over 50,000 critically ill patients annually require mechanical ventilation (MV) in an Australian intensive care unit (ICU) (1). Opioid analgesics (usually Fentanyl) are used to relieve the pain and anxiety associated with IMV but may increase complications from prolonged deep sedation (2,3). In contrast, the ultra-short-acting Remifentanil could provide earlier extubation/ICU discharge and therefore, potentially cost-saving (4). Despite this, the economic disincentive of Remifentanil use in ICU is limited by its acquisition cost (5). Reported economic evaluations demonstrated heterogenous results. Furthermore, there are no published Australian cost-effectiveness analysis (CEA).

**Objectives:** To evaluate the cost effectiveness of Remifentanil compared to Fentanyl in improving quality of life in mechanically ventilated ICU patients from a healthcare perspective.

**Methods:** This was a post-hoc study of a randomised controlled trial (RCT), Remi-fent1 (3). In this study, Health-Related Quality of Life (HRQoL) at six months measured with the EQ-5D-5L instrument was used to calculate outcomes as quality-adjusted life years (QALYs). QALYs were derived by integrating the EQ-5D-5L visual analogue scale (VAS) score with a duration of time. Study data on hospital resource use was used to calculate costs from a healthcare perspective. Primary outcome: Economic evaluation used cost-utility analysis to assess cost-effectiveness overall. The subgroups included sex, age (< 65 vs. ≥ 65 years) and IMV duration (< 72 vs. ≥ 72 h).

**Results:** 210 patients were included (Remifentanil group = 104, Fentanyl group = 106). The overall mean per-patient cost was lower for the Remifentanil group than for the Fentanyl group ($22,306 [$11,157–$51,068] vs. $30,006 [$17,363–$57,868]; $p = 0.006$). The cost-effectiveness of Remifentanil vs. Fentanyl treatment was $192,483/QALY gained. 103 patients were alive at 6 months: No difference in HRQoL; and the mean QALYs gained was similar (0.43 vs. 0.47; $p = 0.11$). The findings were similar by age group, but Remifentanil may be more cost-effective in females than males and those who received IMV for < 72 h.

**Conclusions:** With lower costs and minimal 6-month effects, Remifentanil appeared to be cost-effective compared to Fentanyl. Remifentanil's cost-for-effect trade-off may be deemed 'worthwhile' as an alternative to Fentanyl for better ICU resource allocation. Further evaluation in adequately-powered multi-centre phase-2 trials is required to confirm impacts on longer-term HRQoL and costs outcomes.



* In Australia, the Pharmaceutical Benefits Advisory Committee (PBAC), without a formal willingness-to-pay threshold, deems approximately AUD$50,000 per Quality-Adjusted Life Year (QALY) gained as reasonable value for money.

**(abstract 001490)** Cost-effectiveness plane (CEP): The x-axis denotes the difference in effectiveness and the vertical axis represents the cost difference between the two interventions. The results show that 72% of the 1000 non-parametric bootstrap iterations for Remifentanil fell in the southwest quadrant: lower costs and (perhaps) lower outcomes. The uncertainty surrounding costs and effects due to the statistical variation in both resource use and outcomes was inevitable. Points below this line also represented iterations where remifentanil would be judged as a worthwhile choice over fentanyl

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001492

**Introduction:** The coronavirus disease 2019 (COVID-19) pandemic has led to an unprecedented global health crisis (1). Epidemiology, ventilation management and outcomes of patients with ARDS due to COVID-19 have been reported extensively (2–5), yet these have never been compared amongst patients from different countries.
**Objectives:** To compare epidemiology, ventilator management and outcomes among COVID-19 ARDS patients from Argentina, Brazil, the Netherlands and Spain.
**Methods:** We conducted an individual patient data analysis of four observational studies. The primary endpoint is mortality in the intensive care unit. Secondary endpoints include mortality at 28 and 60 days, and duration of ventilation. We used propensity score weighting to control for observed confounding factors.
**Results:** This analysis included 6702 patients, 1500 from Argentina, 844 from Brazil, 975 from the Netherlands and 3383 from Spain. There were substantial differences in baseline characteristics between countries. There were small differences in ventilation management. ICU mortality was higher in Argentina and Brazil, compared to the Netherlands and Spain (Fig. 1, 59.6 and 56.6% vs 32.1 and 34.7%; P < 0.001). Similar differences existed for the other mortality rates. The median number of days free form ventilation and alive at day 28 was equally low (0 [0 to 7]. 0 [0 to 18], 1 [0 to 16] and 0 [ 0 to 16] days; P = 0.03), the median number of days free form ventilation and alive at day 60 was higher in the Netherlands and Spain (0 [0 to 37], 0 [ 0 to 50], 33 [0 to 48], and 26 [0 to 48] days; P < 0.001). Propensity score matching confirmed the outcome differences.
**Conclusions:** Outcome of COVID-19 ARDS patients in Argentina and Brazil was substantially worse compared to that of patients in The Netherlands and Spain. It is unlikely that this difference results from differences in case mix or ventilation management.

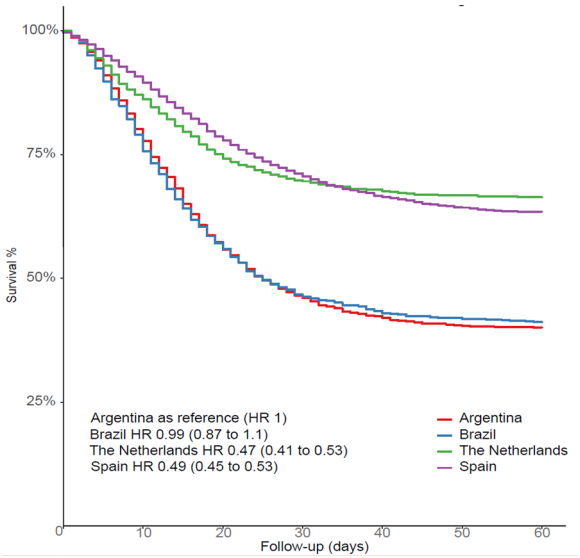

**Fig. 1 (abstract 001492)** Kaplan Meier curves for survival until day 60 in the four countries. HR = hazard ratio

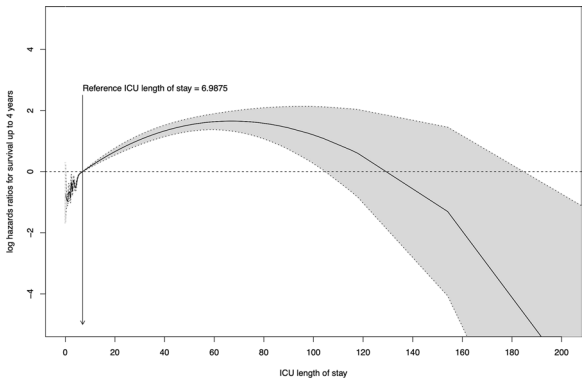
***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001493

**Introduction:** Persistent critical illness (PerCI) is common in patients admitted to intensive care units (ICU). The impact of long-term survival post-cardiac surgery with PerCI is unclear.
**Objectives:** We aimed to investigate the long-term survival of patients with PerCI post-cardiac surgery.

**Methods:** We performed a retrospective, multicentre, cross-sectional study using data submitted to the Australian and New Zealand Intensive Care Society Adult Patient Database from 84 Australian and New Zealand ICUs between 2018–2023. Patients ≥ 16 years post-cardiac surgery and a documented ICU length of stay were included. The presence of PerCI was defined as an ICU length of stay ≥ 7 days. We compared the survival time up to 4 years from ICU admission using time-varying robust-variance estimated Cox proportional hazards models. We further investigated the impact of PerCI as a non-linear predictor of mortality.
**Results:** We included 92,822 patients in the final analysis, and 4497 patients (4.8%) had PerCI. Patients with PerCI had lower four-year (81.5% [95%CI: 80.1–82.9%] vs. 95.0% [95%CI: 94.8–95.1%]; $p < 0.001$) survival rates compared to patients without PerCI. Patients with PerCI had higher mortality (adjusted Hazard Ratio: 2.85, 95%-CI: 2.52–3.22); this was consistent across several sensitivity analyses. When analysed as a non-linear predictor, the hazards of mortality were inconsistent up until seven days, before plateauing up to 100 days of ICU length of stay.
**Conclusions:** In this multicentre retrospective observational study patients with PerCI post cardiac surgery tended to have poorer long-term outcomes. However, the hazards of mortality plateaued beyond the first seven days of ICU stay. Further studies should investigate predictors of developing PerCI, to better prognosticate long-term outcomes.



**(abstract 001493)** Non-linear smooth Hazard ratio curve demonstrating the hazards of mortality were inconsistent up until seven days, before plateauing

**Introduction:** Sepsis survivors are at increased risk of subsequent infection due to persistent immunosuppression; key features include suppressed monocyte HLA-DR expression and lymphopenia [1] Clinical trials using immunomodulatory treatments (e.g. IFN-γ) to restore monocyte HLA-DR have not clearly demonstrated clinical benefit [2].
A possible explanation is that targeting HLA-DR isn't the whole picture; HLA-DR suppression is just one feature of global monocyte dysfunction. Therefore immunomodulatory treatments aimed solely at increasing HLA-DR expression may be insufficient to improve monocyte function [3].
**Objectives:** How do changes in HLA-DR expression after ex vivo stimulation with LPS and IFN-γ relate to global monocyte function.
**Methods:** Peripheral blood mononuclear cells (PBMCs) were isolated from healthy volunteers and from septic ICU patients. To model the monocyte response to a secondary infection, PBMCs were stimulated ex vivo for 24 h with or without LPS, and co-incubated with or without IFN-γ (both 100 ng/ml).
Spectral flow cytometry was used to assess monocyte immunophenotype and function including (i) antigen presentation (HLA-DR/-DP/-DM, CIITA, CLIP, CD80, CD86) (ii) activation (TLR4, NF-κB), (iii) chemotaxis (CCR2), (iv) phagocytosis (FcγR1, NOX-2), (v) cytokine production (TNF-α, IL-1β, IL-10, IFN-γ), (vi) inflammasome assembly (NLRP3), and (vii) T-cell suppression (PD-L1).
HLA-DR expression was compared using the Wilcoxon or Mann–Whitney test (paired and unpaired data, respectively). Monocyte function was analysed using multiple Mann–Whitney tests, and Volcano plots were generated using a false discovery rate of 5%.
**Results:** 24 ICU patients (10 [42%] non-survivors) and 9 volunteers were recruited. [4] Baseline HLA-DR expression was lower in ICU patients ($p < 0.0001$) (Fig a.i.). After the LPS stimulus, HLA-DR increased in volunteers ($p = 0.0039$) but not in patients, consistent with an immunosuppressive phenotype. (Fig a.i.) IFN-γ increased HLA-DR expression in both unstimulated volunteers ($p = 0.0117$) and patients ($p = 0.0385$) (Fig b.i.) and with LPS stimulation ($p = 0.0273$ and $p = 0.0068$, respectively). (data not shown).
In ICU patients, LPS stimulation unmasked multiple defects (all q-values > 1.3) in antigen presentation pathways (HLA-DR, HLA-DP, CD86 and CLIP) and cytokine release (IL-10 and TNF-a) when compared to volunteers. (Fig a.ii. and a.iii., respectively) IFN-γ increased HLA-DR and HLA-DM expression in volunteers but not when co-incubated with LPS. (Fig b.ii.) In ICU patients, IFN-γ had no effect on antigen presentation but increased PD-L1 (Fig b.iii.). Similar effects were seen when IFN-γ was co-incubated with LPS. (data not shown).
**Conclusions:** Monocytes from septic ICU patients display an immunosuppressive phenotype and are unable to respond to a secondary infection.
While IFN-γ treatment increases surface HLA-DR expression in patients it does not modulate other parts of the impaired antigen presentation pathway nor reverse other defective monocyte functions. It does, however, upregulate markers of T-cell suppression (PD-L1), exacerbating the immunosuppressive phenotype.
This may explain why immunomodulatory treatments targeted at increasing monocyte HLA-DR expression have not clearly demonstrated improved outcomes in clinical trials.

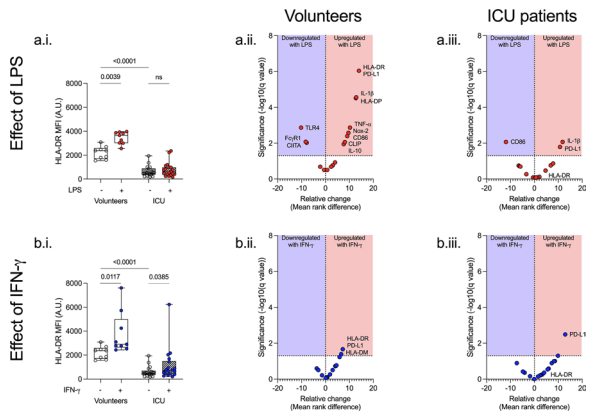

**Fig. (abstract 001493)** LPS stimulation unmasks impaired monocyte HLA-DR expression (a.i.) and function in ICU patients compared to volunteers (a.ii. and a.iii.). IFN-y increases HLA-DR expression (b.i.) but not global monocyte function (b.ii. and b.iii.)

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001497

**Introduction:** Spontaneous intracerebral hemorrhage (ICH) is a common reason for admission to Intensive Care Units (ICU) and it is associated with high morbidity and mortality. Risk prediction of mortality through the use of scoring systems could be important in clinical decisions.
**Objectives:** The purpose of this study was to determine if a scale created with the combination of a severity scoring system commonly used in ICU and a specific score used in patients with ICH, could improve the prognostic capacity in this type of pathology.
**Methods:** Retrospective study of a cohort of patients admitted to the ICU of Gregorio Marañón Hospital (Madrid, Spain) with a diagnosis of spontaneous intracerebral hemorrhage (ICH) between the years 2022–2023. Data collected included demographics and clinical data, severity of illness assessed by APACHE II, ICH score (intracerebral hemorrhage score), as well as by a score created with the combination of both (ICH-APACHE score) and hospital mortality.
Descriptive statistics were expressed as means with standard deviation for normally distributed continuous variables, medians with interquartile range (IQR) for non-normally distributed variables, and percentages for categorical. The ability of the scoring systems to discriminate prognosis was assessed using the area under the receiver operating characteristic (AUROC) curve. Estimation of their calibration was established through the Hosmer–Lemeshow goodness of fit test. Finally, a comparison between the usual scales and the scale created, through the area difference of paired samples under ROC curves, considering the non-existence of differences between scales when the significance was $p > 0.05$.
**Results:** Eigthy-nine patients, 63% male. Age 62 yrs (51–72). Charlson Comorbidity Index 0 pts (0–2). Severity scores: APACHE II 22 pts (16–26), ICHS 3 pts (2–4), Scoring created (ICH-APACHE II) 25 pts (18–29), GCS 10 pts (5–14). Neutrophil-to-lymphocyte ratio 5 (3–11). The supratentorial location was the most frequently observed (75%), with brainstem involvement in 9% of patients, 57% exhibited midline shift and 63% intraventricular bleeding. During ICU stay, 85% of patients needed mechanical ventilation and hospital mortality was 55%.
We confirmed that all severity scores analyzed were predictors of mortality: APACHE II (OR 1.21; 95% CI 1.11–1.33), ICH score (OR 2.28; 95% CI 1.78–4.39), ICH-APACHE score (OR 1.20; 95% CI 1.10–1.30).
Using the AUROC curves (Fig. 1), the ICH-APACHE score on admission was found to be the most reliable scoring system to discriminate hospital mortality (AUROC 0.82; 95% CI 0.73–0.91) with a good calibration ability (Chi-squared 5–23, $p = 0.63$). The results obtained in the others severity scores were: APACHE II score (AUROC 0.80; 95% CI 0.71–0.89) with good calibration ability too (Chi-squared 10.38, $p = 0.24$) and ICH score (AUROC 0.79; 95% CI 0.70–0.88) with good calibration ability too (Chi-squared 1.01, $p = 0.91$). However, there were no significant differences in the ability to discriminate between the scales analyzed (Table 1).
**Conclusions:** Our data suggest that the severity score created, with a combination of different severity scores systems used in critically ill patients with intra-cerebral hemorrhage, does not improve the prognostic predictive capacity of each of them individually.

### Short-term outcomes of extracorporeal cardiopulmonary resuscitation in old age patients with in-hospital cardiac arrest

S. Joo[1], P.J. Kang[1]
[1]Department of Thoracic and Cardiovascular Surgery, ASAN Medical Center, Songpa-gu, Republic of Korea
**Correspondence:** S. Joo
***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001498

**Introduction:** Optimal patient selection is pivotal in improving both survival rates and functional outcomes of extracorporeal cardiopulmonary resuscitation (ECPR). Although advanced age is often considered a relative contraindication for ECPR initiation, the influence of old age on the outcomes of patients treated with ECPR for in-hospital cardiac arrest (IHCA) remains unclear.
**Objectives:** This study aimed to investigate the relationship between advanced age and short-term clinical outcomes of ECPR following IHCA.
**Methods:** Patients aged 65 years or above placed on venoarterial extracorporeal membrane oxygenation (VA-ECMO) for IHCA between January 2018 and December 2022 were retrospectively analyzed.
**Results:** A total of 167 patients were included in the study. Sixty-eight (40.7%) patients were successfully weaned off VA-ECMO, while 99 (59.3%) patients expired on VA-ECMO support. The average age did not show a significant difference between the two groups ($72.7 \pm 6.4$ vs. $74.2 \pm 5.8$; $p = 0.122$). Of the 167 patients, 104 (62.3%) patients were aged between 65 and 75 years and 63 (37.7%) were above 75 years of age. The older group revealed a decreased likelihood of successful weaning from VA-ECMO (20 (31.7%) vs. 48 (46.2%); $p = 0.094$) and a lower survival rate until hospital discharge (14 (22.2%) vs. 39 (37.5%); $p = 0.060$), these differences nonetheless did not reach statistical significance. Moreover, patients within the older group who were successfully separated from VA-ECMO presented a trend towards an unfavorable neurologic outcome, indicated by a greater number of patients with a cerebral performance categories score of 3–5 (24 (50.0%) vs. 16 (80.0%); $p = 0.103$). However, the results were not statistically significant.
**Conclusions:** Although advanced age may demonstrate increased risk with poorer outcomes for ECPR, old age is not an absolute contraindication for VA-ECMO initiation. Patients of old age may require a more thorough evaluation and careful patient selection for optimal ECPR outcomes.

### The effect of exogenous melatonin and melatonin receptor agonists on intensive care unit and hospital length of stay: a systematic review and meta-analysis

A. Kelleher[1], M. O'Donovan[1], D. O'Doherty[2], R. Lavery[3], M. Saab[1]
[1]Medicine and Health, University College Cork, Cork, Ireland, [2]Oncology, Beaumont Hospital, Dublin, Ireland, [3]Cardiology, Mater Private Network Cork, Cork, Ireland

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001499

**Introduction:** Melatonin is a hormone involved in the promotion and regulation of sleep [1]. Disrupted sleep is common in the ICU [2] and is associated with detrimental effects on multiple body systems [3]. Sleep disruption is implicated in the risk for delirium [4] which in turn is associated with prolonged ICU stay [5]. Melatonin supplements and melatonin receptor agonists have been associated with improved sleep for patients admitted to the ICU [6] and lower incidences of delirium [7]. Melatonin and melatonin receptor agonists may therefore have an effect on ICU and/or hospital length of stay.

**Objectives:** The following are the primary objectives for this systematic review:

1. To investigate the relationship between exogenous melatonin or melatonin receptor agonists in the ICU, and ICU length of stay.
2. To investigate the relationship between exogenous melatonin or melatonin receptor agonists in the ICU, and total hospital length of stay.

The review also aimed to address the following secondary objectives:

1. To examine the effect of the dose of exogenous melatonin or melatonin receptor agonist on the length of ICU and/or hospital stay.
2. To examine the relationship between exogenous melatonin or melatonin receptor agonist, ICU and/or hospital length of stay, and patient age.

**Methods:** Six databases and three trial registries were searched for studies relevant to melatonin, ICU and length of stay. Screening was conducted independently by two reviewers, along with the risk of bias assessments and quality appraisals. Meta-analyses were conducted to synthesise the data on the effect of melatonin and melatonin receptor agonists on ICU an total hospital length of stay.

**Results:** Sixteen studies were reviewed. Of those, 13 studies involving 1.903 participants were included in the meta-analysis on the effect of melatonin and melatonin receptor agonists on ICU length of stay. This demonstrated a trend in favour of melatonin but did not reach statistical significance (mean difference [MD] = − 0.29 days [confidence interval (CI) − 0.89, 0.30], $p = 0.332$). Heterogeneity was high across groups ($I2 = 61\%$ [CI 29–79%], $p = 0.002$). The prediction interval indicates that based on current results we can be 95% certain that the MD in the next new study would be between − 2.57 and 1.47 days. Results from subgroups are as follows: melatonin MD − 0.28 days (CI − 0.93, 0.36), $p = 0.387$; ramelteon MD − 1.16 days (CI − 4.6, 2.29), $p = 0.510$.

Ten studies involving 1.930 participants were included in the meta-analysis on the effect of melatonin and melatonin receptor agonists on total hospital length of stay. A non-statistically significant trend in favour of melatonin was again demonstrated (MD = -0.98 days [CI − 2.22; 0.25], $p = 0.118$). Heterogeneity was again significantly high $I2 = 61\%$ [CI 23%–81%], $p = 0.005$). The prediction interval indicates that based on current results. There is 95% certainty that the MD in the next new study would be between − 5.12 and 2.65 days. Melatonin and ramelteon subgroup results are as follows: melatonin MD − 1.31 days (CI − 2.66, 0.05), $p = 0.059$; ramelteon MD 0.71 days (CI − 0.69, 2.11), $p = 0.322$.

None of the included studies examined whether the dose of melatonin or melatonin receptor agonist affected the length of stay in ICU and/or hospital stay. There was considerable heterogeneity between melatonin dosage and frequency of dosing across studies.

None of the included studies examined the relationship between exogenous melatonin or ramelteon treatment, ICU and/or hospital length of stay, and patient age.

**Conclusions:** Melatonin and melatonin receptor agonists were not associated with a reduction in ICU and hospital length of stay. Results should be interpreted with caution due to significant heterogeneity.

### Timing until respiratory support and the next pandemic

F. Simões Ferreira[1], H. Inácio[1], S. Trevas[1], A. Lopes Dos Santos[1], C. Costa[1], M. Lobo Antunes[1], S. Rosado[1], S.P. Carlos[1]

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001502

**Introduction:** The COVID-19 disease is characterized by severe pneumonia in about 20% of patients leading to admission to intensive care (ICU) in 5 to 10% (1). Non-invasive ventilation (NIV) is well known for its usefulness in acute pulmonary edema (APE) and hipercapnic respiratory failure (2) but current guidelines from ERS/ATS are unable to offer a recommendation on the use of NIV for de novo acute respiratory failure (ARF) (3). Nevertheless, during the COVID pandemic, NIV was largely used as a support on its own or as a bridge before invasive mechanical ventilation (IMV). In this study, our aim was to correlate the timing until respiratory support (RS) and patient outcome in an Emergency Department (ED) and define the role of the Intensive Care Unit (ICU) in this setting.
**Objectives:** Primary outcome was defined as the relation between the timing of NIV (< 48 h or > 48 h) and progression to IMV or death at 28 days. Secondary outcome correlated admission clinical variables and outcome.
**Methods:** Observational and retrospective study from March 2020 to January 2021. Inclusion criteria: > 18 years, with COVID disease who had initiated NIV in the ED. Exclusion criteria: patients who had the previous indication for chronic NIV and maintained their usual parameters, NIV for other causes such as APE. A total of 174 patients met these criteria; 60 patients (34.5%) were supported with NIV alone and survived; 114 patients (65.5%) progressed to IMV and/or died. Data was collected from Soarian Clinical software (Siemens) and through bussiness intelligence system information and statistic analysis was made using Excel (Microsoft Corp.).
**Results:** During this period a total of 4685 patients were admitted to the respiratory circuit (RC). The mean length of stay was 30 h in the RC and 9 h in the general circuit (GC) compared with the previous mean of 6 h. Due to insufficient available ventilators RS was delayed and admission in ICU was decided attending not only to clinical criteria but to human resources as well. Of the 114 non-survivors, 49 (42%) used NIV only, all of them unfit for IMV; 42 patients (37%) progressed to IMV and survived while 23 patients (20%) needing IMV died. For the patients who did IMV and survived, the mean time from admission until the start of NIV was 24 h and for IMV up to 50 h. On the other hand, in the group of patients submitted to IMV who died, the mean time from admission until NIV was 32 h and up to 80 h for IMV. There was, therefore, a difference of 30 h before the start of IMV between the 2 groups.
**Conclusions:** During the COVID pandemic the approach to patients with ARF was evolving, attending both clinical criteria and the availability of resources. The timing until NIV and IMV appear to play an important role in this context. A close collaboration between ED and ICU and an acutely ill patient circuit with the collaboration of both teams should be globally worked out. Finally, looking towards the future, ICU resources should be increased to prepare ourselves for the next pandemic.

**Introduction:** Sepsis and septic shock are common in critical care, timely diagnosis and prognosis are of utmost importance. L/Aratio has been studied as a prognostic tool with adequate performance to predict mortality. We evaluated lactate/albumin ratio as a prognostic biomarker (1).
**Methods:** A retrospective cohort was conducted. We included patient records of non-pregnant adults who required mechanical ventilation with ARDS due to viral pneumonia during the 2019 pandemic. Descriptive analysis for baseline characteristics at admission was used, median and interquartile range for continuous variables and percentages for categorical variables. An AUC ROC was calculated for lactate/albumin ratio, SOFA, APACHE II and SAPS II, obtained a cut-off value and OR was calculated with 95% CI and a $p = 0.05$.
**Results:** 76 patients were included, and 98% had respiratory illnesses that required admission to the ICU for mechanical ventilatory support. 63% were males, age 59 years (IQR 52–66), BMI 31 (IQR 27–35), hypertension and DM most common comorbidities (67 and 61%, respectively). MAP 71 mmHg (IQR 84–105). Baseline characteristics of laboratory findings are, lactate 1.3 mmol/l (IQR 1–1.7), haemoglobin 13.3gr/dl (IQR 11.7–14.6), total leukocyte count of 15600cels/mm3, serum albumin 30 mg/dl (IQR 26–33), procalcitonin 2 ng/ml (IQR 2–3) and C-reactive protein of 141 mg/l (IQR 63–241). An AUC ROC was calculated for mortality prognostic performance, values for lactate/albumin ratio, SOFA, APACHE II, SAPS II were 0.706, 0.618, 0.658, 0.844, respectively. With a cut-off point of 0.38 at admission, OR for mortality was 3.55 (CI 95% 1.24–10.14, $p = 0.015$). Both groups had a median mechanical ventilation of 10 days, ICU LOS of 12 days, with lower hospital stay for the superior ratio (16 vs 14 days, $p = 0.19$). Overall mortality was 72%.
**Conclusions:** The L/A ratio is a predictor of in-patient mortality in pulmonary shock septico patient when the use is in the first 24 hours.

**Sepsis-induced alterations in skeletal muscle cell membrane cholesterol**

J.Q. Khoo[1], R. Tidswell[1], W. Pisciotta[1], A. Kleyman[1], M. Singer[1]
[1]UCL, Bloomsbury Institute of Intensive Care Medicine, London, United Kingdom

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001506

**Introduction:** Sepsis is often accompanied by muscle weakness and wasting that affect both short- and long-term outcomes. Serum cholesterol levels fall in septic patients, however, the effects of sepsis on membrane cholesterol across different organs—and their potential contribution to organ dysfunction—remains largely unexplored. Given the critical role of cholesterol in maintaining cellular integrity, signalling, and trafficking, alterations in tissue cholesterol levels may exert a significant influence on organ function.
**Objectives:** Pilot study to investigate skeletal muscle membrane cholesterol levels in samples stored from short-term (faecal peritonitis) and long-term (zymosan peritonitis) rat models of sepsis.
**Methods:** Peritonitis was induced in male Wistar rats (~300 g body weight) by either intraperitoneal injection of faecal slurry ($n = 5$) or zymosan ($n = 16$), a glucan polysaccharide component of yeast cell walls, that produces a more prolonged inflammation. Soleus muscle samples were collected at 6 h in the faecal peritonitis model and at 14 days in the zymosan peritonitis model, immediately frozen and stored at − 80 °C until membrane preparation. Control samples were taken from sham-controlled animals ($n = 8$) at 14 days. Membrane cholesterol levels were quantified using an enzymatic assay (Amplex® Red Assay) and normalised to protein concentration (BCA assay). Statistics were performed using Student's *t*-test, with statistical significance established at $p$ values < 0.05.
**Results:** In the zymosan peritonitis model, a significant reduction in skeletal muscle membrane cholesterol levels was observed at 14 days ($p = 0.02$). Similar results were seen in the more severe faecal peritonitis model at 6 h ($p = 0.019$) (Table 1).

**Table 1 (abstract 001506)** Skeletal muscle membrane cholesterol levels

| | Zymosan peritonitis, 14d | Faecal peritonitis, 6h | Healthy sham |
|---|---|---|---|
| Skeletal muscle membrane cholesterol (µg/µg protein) | 0.068 ± 0.014 (16) | 0.062 ± 0.014 (5) | 0.081 ± 0.012 (8) |
| Comparison vs control | 0.02 | 0.19 | – |

**Conclusions**: The zymosan and faecal peritonitis models of sepsis exhibit differing levels of severity, each resulting in diminished membrane cholesterol at distinct time points (6 h vs 14 days), suggesting different underlying mechanisms. While these findings confirm a decrease in cholesterol levels, further research is needed to establish a causal link between alterations in membrane cholesterol and skeletal muscle dysfunction in sepsis.

### Impact of ATTM, a sulfide donor, on myocardial plasma membrane tissue cholesterol levels in porcine ischaemia/reperfusion injury

A. Al-Thani[1], K. Alotaibi[1], A. Dyson[1], A. Kleyman[1], M. Singer[1]
[1]UCL, Bloomsbury Institute of Intensive Care Medicine, London, United Kingdom

*Intensive Care Medicine Experimental* 2024, **12 (suppl 1)**: 001508

**Introduction:** Plasma membrane cholesterol plays a critical role in maintaining cellular integrity, signalling, and trafficking. Falls in plasmalemmal cholesterol levels exert a significant influence on cardiomyocyte functionality (1). Studies have highlighted a rapid reduction in myocardial cholesterol levels during ischaemic episodes (2). We are investigating the utility of ammonium tetrathiomolybdate (ATTM) in myocardial ischaemia–reperfusion injury. This sulfide donor transiently inhibits mitochondrial respiration, thereby reducing the production of damaging levels of reactive oxygen species. This was protective in ischaemia–reperfusion (I-R) injury rat models of myocardial infarction, stroke and haemorrhage (3).
**Objectives:** To examine the impact of ATTM treatment on myocardial plasmalemmal cholesterol levels in a porcine model of myocardial I-R injury.
**Methods:** Animal studies were performed at the Translational Biomedical Research Centre, University of Bristol. Myocardial infarction was induced in anaesthetised female large white pigs (67 ± 7 kg) by a 60-min balloon occlusion of the distal left anterior descending coronary artery. At 48 min, ATTM 6 mg/kg was infused over 2 min followed by an 18 mg/kg one-hour infusion. Animals were then recovered and monitored for 24 h at which point they were euthanised with hearts taken for histological and biochemical analyses. Tissue samples were collected from distinct heart regions—the infarct zone in the left ventricle, the penumbra surrounding the infarct, and distant areas within the left and right ventricles. The plasmalemmal fraction was isolated and cholesterol was measured by enzymatic Amplex Red Assay. Levels were normalised to total protein (BCA assay). Results were analysed by Student's *t*-test with statistical significance at $p$ values < 0.05.
**Results:** Infarct size was reduced by ATTM (data previously presented). Compared to control pigs undergoing myocardial I-R injury, a non-significant rise in plasmalemmal cholesterol levels was seen at the infarct site, penumbra, and remote right heart of ATTM-treated pigs (Table 1).

**(abstract 001508)**

| Heart area | Control pigs (8) | ATTM treated pigs (7) | *P* value |
|---|---|---|---|
| Infarct site | 0.141 ± 0.053 | 0.211 ± 0.129 | 0.08 |
| Penumbra | 0.147 ± 0.031 | 0.170 ± 0.046 | 0.29 |
| Remote right heart | 0.153 ± 0.075 | 0.203 ± 0.081 | 0.07 |
| Remote left heart | 0.143 ± 0.045 | 0.138 ± 0.053 | 0.97 |

**Conclusions:** Despite a reduction in infarct size with ATTM, only non-significant increases in plasmalemmal cholesterol were detected at the infarct site, the surrounding penumbra, or remote unaffected regions of the heart. Whether these changes have functional significance requires further study.

### Characteristics and acute outcomes of patients presenting with stroke to neurocritical care

M. Miller[1], H. Burgess[1], U. Reddy[1]
[1]Neurocritical Care Unit, National Hospital for Neurology and Neurosurgery, London, United Kingdom
**Correspondence:** M. Miller
*Intensive Care Medicine Experimental* 2024, **12 (suppl 1)**: 001509

**Introduction:** Stroke represents a significant global health challenge, marked by considerable morbidity and mortality [1]. Factors influencing survival among stroke patients encompass age, sex, initial stroke severity, hyperglycaemia, fluctuations in blood pressure and hyperthermia. Despite this, research on stroke patients in neuro-intensive care remains limited.
**Objectives:** This study seeks to profile stroke patients in the neurointensive care unit and explore factors that could influence early stroke mortality.
**Methods:** We reviewed adult patients presenting to a tertiary neurocritical care unit in London between January and December 2023 with a diagnosis of ischaemic stroke, intracerebral haemorrhage (ICH) or non-traumatic subarachnoid haemorrhage. Patients < 18 years, pregnant or breast-feeding patients and those with trauma, tumour or infective intracranial lesions were excluded. The diagnosis was confirmed by neuroimaging. Demographic and clinical data were obtained from the hospital databases. Data were analysed using the GraphPad Prism (Version 10.0.3 for macOS, GraphPad Software, Boston, Massachusetts USA, 2023). Spearman rank correlation coefficient was used to calculate nonparametric correlations between death and sex, type II diabetes, hypertension, dyslipidaemia, atrial fibrillation, delirium, presence of infection, chronic kidney disease, chronic respiratory disease, or requirement for mechanical ventilation.
**Results:** We reviewed 120 patients presenting to neurocritical care; 51 male, 68 female, mean age 56 years, range 16–87 years. Diagnoses included ischaemic stroke (23.3%), intracranial haemorrhage (35%)

and non-traumatic subarachnoid haemorrhage (40%). The vascular territory most affected was supplied by the middle cerebral artery (43.3%), followed by the anterior cerebral artery (20.8%). Patients were admitted to ICU for mechanical ventilation (69.2%), neurological complications (e.g. low GCS, hydrocephalus, vasospasm and seizures) (58.3%), cardiac complications (11.6%), respiratory complications (e.g. pneumonia, aspiration pneumonitis and pulmonary embolism) (26.7%) and others (e.g. diabetic ketoacidosis, hyponatraemia) (4.16%). Nearly half (47.5%) of the patients were transferred from other hospitals with 5% being a direct ICU referral. 92.5% of patients had an initial modified Rankin score of 0 or 1 indicating a high baseline level of functioning. In total, 69.2% of required mechanical ventilation either for management of low Glasgow Coma Score (30.8%), to facilitate surgical management, or to manage specific complications e.g. severe agitation or bulbar dysfunction.

Median ICU length of stay was 8 days (IQR 12, range 1–70) and the hospital length of stay was 21 days (IQR 37, range 1–427). 20% of patients died in ICU, 14.1% due to a cardiac death and 5.8% due to brainstem death. In-hospital mortality was 25.8%, though this may not reflect actual mortality as patients were often repatriated to their base hospitals. Acute mortality in stroke patients correlated strongly with hypertension ($p < 0.004$, CI -0.4288 to -0.08351) and mechanical ventilation ($p < 0.0001$, CI 0.1664 to 0.4950).

**Conclusions:** Hypertension and the need for mechanical ventilation were identified as risk factors for acute mortality after ICU admission for stroke.

## A single centre review of practices managing right ventricular dysfunction in patients with an Impella

A. Harris[1], G. Gallagher[2]
[1]Intensive Care, St Mary's Hospital, London, United Kingdom, [2]Intensive care, Royal Free London NHS Foundation Trust, London, United Kingdom
**Correspondence:** G. Gallagher
***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001512

**Introduction:** Right ventricular (RV) dysfunction is an independent predictor of mortality in left ventricular (LV) dysfunction1. Although primarily a device to manage the left ventricle (LV), the Impella has been shown to improve RV function by a series of proposed physiological mechanisms pertaining to interventricular dependence, preload, and afterload2,3. However, there is little evidence of successful strategies to manage the complexities of coexistent RV dysfunction for patients with an Impella in situ.
**Objectives:** Review methods used to manage RV dysfunction in patients with an Impella in situ to investigate if there were trends in management that conferred better outcomes.
**Methods:** The local mechanical circulatory support (MCS) registry at Harefield Hospital was used to retrospectively review data. Between January 2019 and October 2022, all patients admitted to Harefield Hospital intensive care unit who had an Impella placed as part of their management, were reviewed for incidences of RV dysfunction. RV dysfunction was diagnosed on transthoracic or transoesophageal echocardiography. Their management plans and pharmacological therapies were reviewed, and their outcomes were recorded.
**Results:** During the 46-month period, 67 patients had an Impella placed. 39 patients (58%) were diagnosed with RV dysfunction, of which there was a 69% 30-day mortality rate. Management strategies for RV dysfunction included single and combined use of inodiltators (such as milrinone, levosimendan), pulmonary vasodilators (epoprostenol; inhaled therapies such as nitric oxide); and escalation to other MCS, such as extracorporeal membrane oxygenation (ECMO) and ventricular assist devices (VADs). Principal findings were that:

- 7.5% of patients were not given any pharmacological or mechanical management for their RV dysfunction, and all of these patients fell into the mortality group.
- 20% were managed with single therapy milrinone and there was an equal distribution between survival and mortality.
- Multimodal pharmacological therapy was more common in the mortality group with 33% compared with 8.5% in the survival group.
- Of the patients who escalated to other MCS, there was a 61% mortality rate.

**Conclusions:** Non-pharmacological cardiac support is now provided by a range of technologies. Their adoption needs careful consideration given the many facets of concurrent pathologies in these patients. There is an inconsistent approach to patients with RV dysfunction and the use of this form of LV support. They are an under-investigated group, and these results highlight the significant level of mortality in patients with RV dysfunction whilst on Impella support. A lack of treatment is linked with poor outcomes, but other treatment plans show varying outcome results. This is a group of patients with complex physiology and multifactorial organ dysfunction. With such a high mortality rate in this cohort, establishing a consistent approach to their cardiac pathology needs to be established and may yield improved outcomes.

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001515

**Introduction:** Acute Kidney Injury (AKI) refers to the sudden loss of renal function determined by an increase in baseline creatinine levels greater than 0.3 mg/dl or an increase of 50% in creatinine serum levels. AKI is very common in the intensive care unit with an incidence of 30–60% and is considered a poor prognostic factor in critically ill patients.
In animal models, IL-6 and lymphocyte transcription and signaling were found to be elevated locally and systemically after 60 min of bilateral renal ischemia. This finding indicated that IL-6 and lymphocyte signaling may be employed as a biomarker and therapeutic target in AKI. Various diseases such as Acute Respiratory Distress Syndrome (ARDS) have increased serum levels of IL-6 and lymphocytes and may predispose to AKI.
There are no studies associating the IL-6 / Lymphocyte ratio with the development of AKI in critically ill patients with severe ARDS.
**Objectives:** Determine the association between the IL-6 / Absolute Lymphocyte Index upon admission to the ICU and the development of Acute Kidney Injury according to KDIGO in patients diagnosed with severe ARDS.
**Methods:** Retrospective cohort study. Patients over 18 years old who were admitted to the intensive care unit with a diagnosis of severe ARDS were included. For qualitative variables, the chi-square test ($\chi^2$) was used, for normally distributed quantitative variables, Student's *t*-test, while for non-normally distributed quantitative variables, the Mann–Whitney *U* test was used. To determine the association of biochemical markers, clinical status upon hospital admission, and the development of AKI, an unadjusted logistic regression was performed to identify variables with the greatest impact. These variables were then used to construct a multiple logistic regression model.
**Results:** A total of 98 patients were included, of whom 53 (54.1%) were male, with a mean age of 61.5 years ($\pm$18.0) and 39.8% of patients developed AKI (Table 1). In the unadjusted logistic regression, the variables with the greatest impact were IL-6 > 1169.0 pg/mL OR of 5.6 (95% CI 0.5, 57.1), and the IL-6/Lymphocytes index > 170.1 OR of 2.4 (95% CI 0.7, 7.9) (Table 2). When adjusting for age using multiple logistic regression, the IL-6/Lymphocytes index > 170.1 had an OR of 2.2 (95% CI 0.6, 8.1), and age > 68 years had an OR of 17.76 (95% CI 1.5, 198.9), with an r2 value of 0.142. (Table 3).
**Conclusions:** In this retrospective study, an association was found between elevated levels of IL-6 and the development of Acute Kidney Injury (AKI) in patients diagnosed with severe Acute Respiratory Distress Syndrome (ARDS). Additionally, it was observed that a high IL-6/Lymphocyte ratio could also be related to a higher risk of AKI. These findings suggest that assessing these biomarkers upon admission to the intensive care unit could be useful in identifying patients with severe ARDS who are at increased risk of developing AKI, thereby allowing for early intervention and improved clinical outcomes.

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001517

**Introduction:** Esophageal pressure (Pes) is the reference method to measure respiratory muscle pressure during assisted breathing. The recording of Pes is difficult and fraught with potential errors, i.e.: changes at elastance of the respiratory system. Tracheal Pressure (Ptrach) may be an alternative since it contains information on pleural pressure. The inflection points in its first derivative (Ptrach') could reflect changes in acceleration generated by patient effort and, therefore, in pleural pressure.
**Objectives:** Our objective was to study the relationship between Ptrach´ and Pes signals in the frequency and time domains.
**Methods:** Physiological study in a group of patients during the withdrawal period of mechanical ventilation at different levels of pressure support (PSV). Airway pressure (Paw), Flow, Esophageal pressure (Pes), and Tracheal pressure (Ptrach: Intratracheal pressure sensor M1045564®, Carefusion, Finland) signals were analyzed from files previously recorded for clinical purposes. Sampling 1126 Hz. Measurements: Calculate respiratory mechanics, Ers and Rrs at different levels of assistance through pauses and time constant. Calculate the first derivative of Ptrach (Ptrach. Computation of spectral frequency using fast Fourier transform (FFT). Coherence analysis (MSC) of the spectral density of both signals (minimum variance distortion method). Cross-correlation coefficients at time 0 (Lag 0) and the point of maximum correlation between both signals. Data were expressed as means ± SD or medians and IQR; and comparisons using the Mann–Whitney test.
**Results:** 10 patients were studied. The complete signals were described by three harmonics (H). Global energy distribution Pes vs Ptrach´ (cmH2O2): 1ºH (0.24 Hz) $12.56 \times 103$ vs $9.55 \times 103$ $p = 0.88$; 2ºH (0.43 Hz) $5.01 \times 103$ vs $6.77 \times 103$ $p = 0.30$; 3ºH (0.69 Hz) $17 \times 103$ vs $3.45 \times 103$ $p = 0.34$. MSC for all levels of assistance: 1ºH, 0.93 (0.74–0.99); 2ºH, 0.95 (0.89–0.98); 3ºH, 0.93 (0.72–0.96). Cross-correlation at Lag0: R 0.68 (0.54–0.85) vs max R 0.70 (0.58–0.86) at Lag + 20 (0.02 s). Representative case are shown in figure.
**Conclusions:** Monitoring the first derivative of tracheal pressure can reflect patient effort equivalent to esophageal pressure during pressure support ventilation.

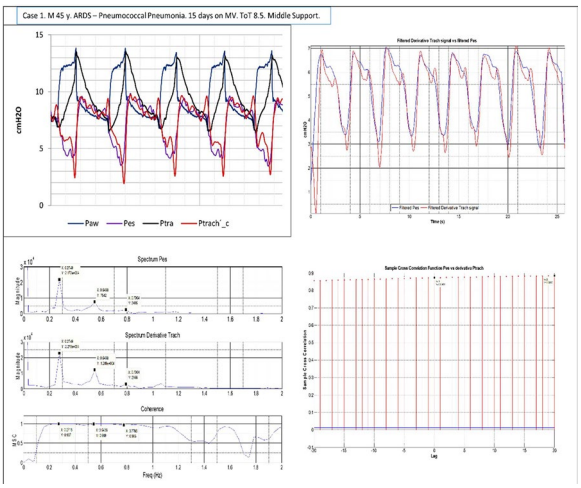

**Fig. (abstract 001517)** Patient 1. A representative case of methodology and results shows a similarity between esophageal pressure and the first derivative of tracheal pressure

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001521

**Introduction:** We are facing an increase in cancer diagnosis, with some estimates by the WHO organization predicting 29.4 million new cancer cases in 2040. Recent advances regarding potential for treatment have been associated with an upturn in intensive care (ICU) admissions. Whether this is coupled with improved outcomes is a matter of debate, but some studies suggest a mortality reduction. Persistent doubt might be related to missing data regarding outcome or survival prediction in oncological ICU patients.
**Objectives:** Characterize ICU admissions and outcomes of all adult patients pertaining to a diagnosis of solid malignancy over a 10-year period.
**Methods:** Retrospective single-center study conducted in a tertiary oncological referral hospital. Between 2014 and 2023, all non-elective ICU admissions of patients with a solid malignancy diagnosis were included. Primary central nervous system malignancy was excluded. Type and stage of malignancy, clinical condition and organ failure at admission, severity scores, ICU and hospital mortality were evaluated. Parametric tests using X2 were used to study associations with mortality. A $p$-value < 0.05 was considered to have statistical significance.
**Results:** During the study period, a total of 152 patients with solid malignancy were admitted to our ICU. Most patients were male (61%), median age was 68.7 ± 13 years. The most common malignancies were colon and rectal cancer (32%), lung cancer (19%) and gastric cancer (8%). Regarding cancer stage, 59% had low-intermediate stage (I-III) and 41% had stage IV cancer. Type of admission (medical vs surgical) was similar (51% vs 49%). The most common reason for admission was respiratory failure (35%), with a need for invasive mechanical support (IMV) occurring in 76.7% of cases. Acute kidney injury occurred in 56% (continuous renal replacement therapy performed in 10%) and septic shock was reported in 30%. Mean length of ICU stay was 6.7 ± 12 days and mean length of hospital stay was 26.6 ± 28.5. Mean SAPS II score was 48 ± 18. Overall ICU and in-hospital mortality was 30% and 44%, respectively. Highest mortality was seen with liver and bile duct cancer (67%) and lung cancer (51%); it was also associated with higher SAPS II (64 ± 17) and SOFA (10 ± 4) scores, a higher percentage of IMV (87%), higher incidence of AKI (70%) and septic shock (43%). Stage IV cancer patients had a higher ICU mortality vs low-intermediate cancer (46% vs 20%; $\chi^2 p < 0.001$). Higher mortality was seen in patients with a medical vs surgical condition as the main reason for admission (57% vs 30%; $\chi^2 p < 0.01$). There was no difference in mortality regarding age or gender.
**Conclusions:** Overall prognosis of patients with a solid malignancy diagnosis at ICU admission remains ominous, with medical-related factors and advanced cancer stage imputing a higher risk of mortality. This suggests that prevention of medical complications, like infection or thrombosis, might be the most impacting factor in reducing the mortality of these patients.

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001523

**Introduction::** Inhalation injury in burns was the most frequent cause of acute respiratory failure (ARF) requiring mechanical ventilation, and increased mortality by 20–70%. [1] Knowledge of risk factors for invasive mechanical ventilation in burns with inhalation injury was crucial for the management of these patients.
**Objectives:** to determine risk factors for invasive mechanical ventilation (IMV) in burns with inhalation injury.
**Methods:** A retrospective descriptive comparative study was conducted in an intensive burn care unit in Tunisia over 4 years (January 2018 and December 2021) focusing on burned patients with pulmonary burns. Patients were divided into two groups: those who were ventilated (MV+) and those who were not (MV−).
Diagnosis of inhalation injury was retained by the presence of at least 2 of the following criteria: fire in an enclosed space, the presence of soot in the oropharynx or sputum, respiratory symptoms associating dry cough, dysphonia with hoarseness of voice, wheezing, ronchi and sibilant, and the presence of facial burns. Bronchial fibroscopy was the reference exam for diagnosis [1].
**Results:** During the study period, 1200 patients were admitted, 130 of whom presented inhalation injuries. The mean age was 42 ± 7 years, with a sex ratio of 3.6. The mean SOFA score was 3.7 ± 2.8. APACHE was 14 ± 6.1. Total body surface area (TBSA) was 38 ± 15%. Burns were profound with an UBS score of 58.5 ± 20.5. Thermal burns were frequent affecting 92% of patients, followed by suicide attempts in 42% of cases. 72 patients required mechanical ventilation (55%), with a delay of 2 days after burns. The mortality in this group (MV+) was 35% vs 14% in (MV-) group.
Risk factors associated with mechanical ventilation in multivariate analysis were: presence of face and neck edema ($p = 0.01$RR 3.991, IC95% [1.02; 4.738]); occurrence of shock ($p = 0.001$, RR 8.1, IC95% [2.12; 9.843]; delay of secondary transfer > 3.2 days ($p = 0.02$ OR = 8.913 IC95% [1. 13–70.32]), UBS score > 61 ($p = 0.03$ OR: 1.04, IC 95% [1.01–1.08];), occurrence of pneumoniae ($p = 0.04$, OR: 1.07 IC 95% 1.00–1.14].
**Conclusions:** In burns with inhalation injury, predictive factors for invasive mechanical ventilation were the presence of oedema of the face and neck, the occurrence of shock, the occurrence of pneumoniae, an UBS score > 61 and transfer time > 3.2 days.

**Correspondence:** J.E. Guerra Souza
***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001525

**Introduction:** Determining risk in patients undergoing cardiac revascularization surgery is essential for clinical management and prognosis. SAPS 3, APACHE II and EuroSCORE II prognostic scores are widely used, however, their relative effectiveness in predicting outcomes such as a death in the intensive care unit (ICU) requires rigorous comparative evaluation.
**Objectives:** To retrospectively investigate the accuracy of SAPS 3, APACHE II and EuroSCORE II scores in predicting the primary outcome of death in the ICU in patients undergoing myocardial revascularization surgery, with emphasis on the superior performance of SAPS 3.
**Methods:** A retrospective study was conducted in a Quaternary University Hospital specialized in cardiac surgery. Adult patients who underwent myocardial revascularization were included. SAPS 3, APACHE II and EuroSCORE II scores were calculated using data from the first 24 h after ICU admission. Accuracy was assessed by the area under the ROC curve (AUC), and calibration was analyzed using the Hosmer–Lemeshow test.
**Results:** The analysis comprised a significant cohort of patients. The results revealed that SAPS 3 had the highest accuracy in predicting death in the ICU, with a higher AUC compared to the APACHE II and EuroSCORE II scores. Furthermore, SAPS 3 demonstrated adequate calibration, indicating alignment between score predictions and observed outcomes.
**Conclusions:** This retrospective study highlighted the superior performance of SAPS 3 in relation to APACHE II and EuroSCORE II scores in predicting death in the ICU in patients undergoing cardiac revascularization surgery. These findings suggest that SAPS 3 may be the most appropriate prognostic score for risk stratification in this specific population, contributing to a more precise and targeted clinical approach.

**Introduction:** Traumatic brain injury (TBI) still is a major cause of mortality and disability Worldwide. Ageing population is correlated with a higher prevalence of cardiovascular diseases requiring antiplatelet and anticoagulation therapy. The intake of these medications can increase the risk of intracerebral haemorrhage and subsequently outcome and mortality rate.
**Objectives:** This study aims to analyse the effect of antiplatelet and anticoagulation therapy on functional outcomes and mortality in TBI patients.
**Methods:** This is a retrospective observational study of adult TBI patients admitted to the general ICU in a tertiary hospital between 2021 and 2023. The two groups were categorised according to the presence or absence of antiplatelet and anticoagulation therapy (AAT vs non-AAT). Collected data included demographics, comorbidities, type of trauma and brain injury, Glasgow Coma Scale Score (GCS) on ICU admission, neurosurgical intervention, length of stay (LOS), functional outcome and mortality. The main analysis considered hospital mortality and functional outcome at 6 months, defined by Glasgow Outcome Scale (GOS), considering unfavourable GOS 1–3 and favourable GOS 4–5, between the two groups.
**Results:** A total of 82 patients with TBI were included in this study, with a male prevalence of 79% vs 21% female. Twenty-two patients were under AAT prior to TBI. The most elderly patients were observed in the AAT group, mean age $72.8 \pm 9$ years and 86% aged $\geq 65$ years compared with $57 \pm 16$ years and 35% in non-AAT, respectively. Hypertension (82% vs 32%), dyslipidemia (55% vs 27%), coronary artery disease (41% vs 13%) and atrial fibrillation (18% vs 2%) were the most represented comorbidities in AAT patients. The severity of TBI, considering a GCS < 9, was higher in AAT 73% vs 63% in non-AAT group. Intraparenchymal haemorrhage was the most common injury in patients with AAT (73% vs 57% non-AAT) and craniectomy was the most common surgical procedure (27% vs 10% non-AAT), followed by craniotomy (32% AAT vs 33% non-AAT). The overall hospital mortality rate was significantly higher in AAT (77% vs 45%, $p = 0.026$). When analysing patients with $\geq 65$ years, no differences were found between both groups in terms of mortality (78% AAT vs 52% non-AAT, $p = 0.071$). Patients with $\geq 65$ years had a higher mortality rate regardless antiplatelet and anticoagulation therapy (64% vs 40% < 65y, $p = 0.028$). In terms of functional outcome, there was no statistical difference in favourable GOS at 6 months between the two groups (16% AAT vs 33% non-AAT, $p = 0.146$).
**Conclusions:** In the studied population, antiplatelet and anticoagulation therapy was associated with higher overall mortality, but no difference was seen in patients over 65 years between both groups. Also there was no difference in terms of functional outcome at 6 months. As a limitation, the study had a small sample and a great heterogeneity of ages which can lead to bias. Further studies are necessary to determine the impact of antiplatelet and anticoagulation therapy in TBI patient's outcome.

### Evaluation of throboprophylaxis and risk of venous thromboembolic disease in patients with ischemic cerebrovascular accident using the PADUA Scale

R. Villa[1]
[1]Intensive Care, Policlínico del Docente, Cdad. Autónoma de Buenos Aires, Argentina
**Correspondence:** R. Villa
***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001528

**Introduction:** STROKE is a public health problem of the first order. In addition, it is the leading cause of permanent disability in adulthood. Many of the patients who survive suffer significant sequelae that limit their activities of daily living. One of the pillars in secondary prophylaxis is anticoagulation, either due to the patient's own comorbidities or neurological sequelae that limit mobility. We used the Padua Scale to describe the risk of VTE in these patients, as well as assess the use of antithrombotic prophylaxis.
**Objectives:** To evaluate the usefulness of the PADUA scale for thromboprophylaxis and the development of thromboembolic disease in patients with stroke.
**Methods:** Descriptive, cross-sectional, analytical, retrospective study. Twenty-four clinical histories of people over 18 years of age admitted to the critical care unit, with a main diagnosis of ischemic stroke, were reviewed during the period from January 1 to August 30, 2023. Cases with a different main diagnosis, incomplete records were excluded. transferred to other centers and voluntary withdrawals. ****** Data on comorbidities, previous vascular events, NIHSS at admission, thrombotic events and intra-hospital thromboprophylaxis, as well as the presence of some type of bleeding or other complications were extracted. Descriptive and analytical statistics were performed with Student's $T$ for quantitative variables and Chi2 test for qualitative ones with SPSS IBM v. 23.0, values of $p < 0.05$ were considered statistically significant.
**Results:** With a predominance of women (58.3%), and a mean age of the entire sample of 62.25 years (41–92 years), it was found that the most frequent morbidities were Hypertension (95.8%) and type 2 DM (45.8%), followed by previous stroke (20.8%). In the entire sample, 70.8% of the patients received thromboprophylaxis during hospitalization, either initially or during hospitalization. Using the Padua Scale, 58.3% of the patients showed a High Risk of presenting VTE in the future, of which 85.7% received thromboprophylaxis ($p$: 0.000, CI: 0.000–0.001). Using the initial NIHSS Scale of the patients, 66.7% presented Moderate Stroke, of which 92.85% of the patients presented a High Risk of developing VTE ($p$: 0.018, CI: 0.008–0.012). None of the patients evaluated presented a thromboembolic event during hospitalization, as well as any type of bleeding complication.
**Conclusions:** Most of the patients who develop Stroke already receive thromboprophylaxis during hospitalization, either at the beginning or during the hospitalization. Patients with moderate Stroke have a higher risk of developing venous thromboembolic disease, so they would benefit from thromboprophylaxis both during hospitalization and at discharge. It would be very useful to use the NIHSS and Padua Scales together to describe the risk of VTE and assess the use of antithrombotic prophylaxis.

### Influence of respiratory system compliance on inspiratory effort and ventilatory drive in COVID-19 patients

B.A. Marcos[1], A.C. Cardoso Dos Santos[1], L.B. Oliveira[1], A.C.A. De Sousa[1], E. Ceron[1], C.S.V. Barbas[1]

**Correspondence:** A.C. Cardoso Dos Santos
***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001529

**Introduction:** Pleural pressure can be estimated by esophageal pressure measured with an esophageal balloon, which is the gold standard

for assessing muscle pressure during spontaneous breathing. In critically ill patients, factors such as pain, anxiety, discomfort, acidosis can significantly impact ventilatory drive. A previous study evaluated the potential association between inspiratory effort and respiratory system compliance according to two different levels of PEEP and identified that high peep could reduce inspiratory effort if compliance increased. Yet, knowledge regarding the influence of respiratory system compliance on inspiratory effort and ventilatory drive is still limited. This study aims to elucidate any potential correlation between these variables.

**Methods:** This prospective cohort study was approved by the institutional ethics committee. Fifteen patients with ARDS due to COVID-19 during the mechanical ventilation weaning phase were submitted to four levels of pressure support (15-10-5-0cmH2O) for 20 min each step, data were collected at the final of each step. Esophageal balloon was used, Baydur maneuvers were considered to check the balloon position (adequate slope range 0.8–1.2)4. The software LabVIEW was used to analyze the tracings. We categorized groups by high and low respiratory system compliance (median 34.8 mL/cmH2O). Linear mixed-effects model fit by REML was performed using R 4.2.2 (R Foundation for Statistical Computing, Vienna, Austria; http://www.r-project.org). P values < 0,05 were considered statistically significant.

**Results:** The variables exposed did not show statistical differences between the two groups. Graph A—Pmus presented a wider variation in the LowCrs group [from 6.49 (1.49) to 11.7 (1.39) cmH2O]. Graph B—P0.1 showed a similar variation in the two groups (average difference of 0.22 cmH2O), the LowCrs group started the protocol with higher values of P0.1 [starting at -3.37 (0.47 cmH2O)]. Data is plotted as the mean and standard error of the mean (SEM) and individual values.

**Conclusions:** The data suggests that Crs may not have a direct impact on muscle effort, although P0.1 was, significantly, more pronounced in the LowCrs group. To mitigate adverse outcomes during the weaning phase, it is crucial to monitor respiratory drive, effort, and their influencing variables closely. Further research on this topic is necessary.

**Table 1 (abstract 001529)** Groups were divided by LowCrs: Low chest wall compliance and HighCrs: High chest wall compliance. Data are shown as mean and standard error of the mean (SEM); and Crs: respiratory system compliance and PS: pressure support *p* values. ΔPmus: Delta of respiratory muscle pressure; P0.1: negative airway pressure generated during the first 100 ms of an occluded inspiration (respiratory drive representative).

### Outcomes of chronic critical illness in a Portuguese ICU

A.C. Oliveira[1], J. Serras Almeida Nunes[1], S. Pina[1], R. Marques[2], A. Binnie,[3], J. Moreno[1], S. Castro[1]
[1]Serviço de Medicina Intensiva 1, Centro Hospitalar Universitário do Algarve, Faro, Portugal, [2]Serviço de nefrologia, Centro Hospitalar Universitário do Algarve, Faro, Faro, Portugal, [3]Critical Care Medicine, William Osler Health System-Etobicoke General Hospital, Toronto, Canada
**Correspondence:** A.C. Oliveira
***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001530

**Introduction:** Advances in intensive care medicine have reduced the mortality rate of ICU patients. However, many patients who survive the initial period of critical illness require organ support for a prolonged period and become chronically critically ill. The definition of chronic critical illness is not uniform; the most frequently cited criteria are mechanical ventilation > 3 weeks and/or tracheostomy. More recently, an ICU stay of more than 8 days associated with one of 6 conditions

(invasive mechanical ventilation, tracheostomy, stroke, head trauma, sepsis or serious injury) was also considered [1], [2].

**Objectives:** To determine the incidence of chronic critical illness and its outcomes in a Portuguese intensive care unit. To identify predictors of survival amongst patients with chronic critical illness.

**Methods:** Single-center retrospective observational study of patients admitted to the polyvalent ICU in Portugal for ≥ 3 weeks in 2023. Demographic and clinical data were extracted from the electronic medical record.

**Results:** Out of 495 patients admitted to the ICU in 2023, 53 (10.7%) had ICU admissions lasting ≥ 3 weeks. Amongst these, the mean age was 58.2 ± 17.4 years and the majority were male (73.6%). The mean length of ICU stay was 34.9 ± 14.6 days and the mean length of hospital stay was 93.9 ± 64.4 days.

The most frequent admission diagnoses were sepsis (30%), trauma (27%), and neurocritical illness without trauma (32%) (Fig. 1). The median SAPS II score on admission was 51, representing severe illness. ICU mortality was 24.5% with survivors staying in the hospital for an average of 80.35 ± 67.17 days. In-hospital mortality was 47.1%.

At 3 months, overall mortality was 55.1%. Amongst hospital survivors, only 8 (15%) were living at home. The rest were discharged to rehabilitation units, with the exception of 4 patients (7.5%) who were lost to follow-up.

To identify factors predicting ICU survival in chronic critical illness, we tested a multivariable logistic regression model including age, sex, admission diagnosis, illness severity at admission (SAPS II) and days of hospitalization prior to ICU admission as predictor variables. Among the patients who survived and those who died, age was the only variable that showed a statistically significant difference between the two groups (*p*-value 0.002) (Table 1).

**Conclusions:** In this single-center study, chronic critical illness was associated with prolonged hospitalization and high mortality. Younger age was the only variable that was associated with improved survival. Further studies will be required to identify variables that predict survival and good functional outcomes as well as to identify potential modifiable risk factors.

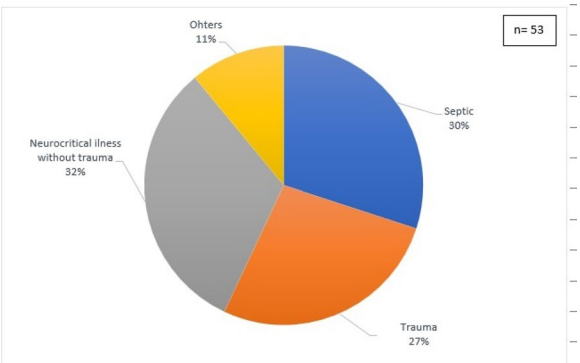

**Fig. 1 (abstract 001530)** Admission diagnoses

**Table 1 (abstract 001530)** Factors predicting ICU survival.

| Characteristic | Died, N=24[1] | Survived, N=25[2] | p-value |
|---|---|---|---|
| Age (years) | 65.54 (16.37) | 51.92 (16.03) | 0.002 |
| Sex | | | 0.6 |
| Male | 18/24 (75%) | 17/25 (68%) | |
| Female | 6/24 (25%) | 8/25 (32%) | |
| Admission diagnosis | | | 0.2 |
| Septic | 10/24 (42%) | 5/25 (20%) | |
| Neurocritical illness without trauma | 8/24 (33%) | 8/25 (32%) | |
| Trauma | 3/24 (13%) | 9/25 (36%) | |
| Others | 3/24 (13%) | 3/25 (12%) | |
| SAPS II | 52.75 (13.38) | 46.04 (14.35) | 0.12 |
| Admission prior to ICU (days) | 7.17 (13.99) | 2.40 (3.58) | 0.4 |

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001531

**Introduction:** Acute exacerbation of patients with COPD needing hospitlisation in the Intensive care unit (ICU), may require the use of invasive mechanical ventilation (IMV) and therefore, can be associated with a high risk of mortality. Currently, there is no reliable, credible and reproducible method available to assess mortality risk upon admission.

**Objectives:** to assess different COPD scoring systems to predict in-hospital mortality and the need for IMV in AECOPD patients hospitalized in the ICU.

**Methods:** We retrospectively included patients hospitalized for AECOPD in the intensive care unit department of Abderrahmen Memi Hospital from October 2023 to February 2024. We compared 5 scoring systems predicting the need for mechanical ventilation and mortality: CAUDA-70 (Confusion, Acidosis pH < 7.35, Urea > 7 mmol/l, MRC > 4, Albumin < 35 g/l and age > 70 years), NEWS (respiratory rate > 30, oxygen saturation < 91%, need for supplemental oxygen, temperature, systolic blood pressure < 90 mmhg, heart rate > 131 and level

of consciousness < 10), DECAF (Confusion, Urea > 7 mmol/l, Respiratory rate > 30, hypotension, 65 Years above), HACOR (heart rate > 121, CG < 10, respiratory rate > 46, PaO2/FiO2 < 100, pH < 7.25) and CAPS (The COPD and Asthma physiological score from 0 to 100 points) scores.
**Results:** During the study period, 50 patients were hospitalized for AECOPD. They had a male predominance (82%) with a mean age of 66 years. The need for IMV was 52% and the total in-hospital mortality was 40%.
NEWS and HACOR score were associated with a significant prediction of IMV (respectively, $p = 0,03$; AUC: 0,67; IC [0,52;0,825], ($p = 0,03$; AUC: 0,67; IC [0,51;0,82]), while DECAF, CAUDA-70 and CAPS scores were not [ ($p = 0.08$), ($p = 0.57$), ($p = 0.1$), respectively]. No score was significantly associated with the occurrence of in-hospital mortality.
**Conclusions:** The NEWS and HACOR scores outperform other scores in predicting the need for MV in AECOPD patients. Therefore no score was predictive of the occurrence of in-hospital mortality. Larger studies are required for better evaluation of these scores.

### Temporalis muscle thickness and functional outcome in patients with ischemic stroke

Y.S. Kim[1]
[1]Neurology, Korea University Guro Hospital, Guro-gu, Republic of Korea
**Correspondence:** Y.S. Kim
*Intensive Care Medicine Experimental* 2024, **12 (suppl 1)**: 001533

**Introduction:** Stroke is one of the leading causes of skeletal muscle loss and sarcopenia due to inactivity, immobility, and malnutrition during hospitalization. However, because of the difficulty of measuring muscle mass during acute stroke treatment, sarcopenia in stroke patients has not been extensively studied. Recently, temporal muscle thickness (TMT), which can be easily measured by brain imaging, has been proposed as a practical marker of sarcopenia.
**Objectives:** To determine whether TMT is associated with functional outcomes in patients with ischemic stroke.
**Methods:** Patients with ischemic stroke who transferred to the rehabilitation medicine department after acute stroke treatment between 2021 and 2022 were included in the study. Non-contrast CT, CT angiography, or T1-weighted image of MRI obtained during hospitalization was used to assess TMT. When a patient had multiple scans, the scan closest to the initiation of the comprehensive rehabilitation program was selected preferentially. TMT was measured bilaterally perpendicular to the long axis of the temporalis muscle in a slice 5 mm above the orbital roof, and the average of the bilateral measurements was used for the analysis. The primary outcome of the study was the Modified Barthel Index (MBI) at the time of discharge after a comprehensive rehabilitation program. Modified Rankin Scale (mRS) at 3 months after stroke onset was further assessed. Good functional outcome at 3 months was defined as an mRS score of 0 to 2. Multivariable linear regression and multivariable logistic regression analyses were performed to examine the association between TMT and functional outcome. Patients with ischemic stroke who transferred to the rehabilitation medicine department after acute stroke treatment between 2021 and 2022 were included in the study. Non-contrast CT, CT angiography, or T1-weighted image of MRI obtained during hospitalization was used to assess TMT. When a patient had multiple scans, the scan closest to the initiation of the comprehensive rehabilitation program was selected preferentially. TMT was measured bilaterally perpendicular to the long axis of the temporalis muscle in a slice 5 mm above the orbital roof, and the average of the bilateral measurements was used for the analysis. The primary outcome of the study was the Modified Barthel Index (MBI) at the time of discharge after a comprehensive rehabilitation program. Modified Rankin Scale (mRS) at 3 months after stroke onset was further assessed. Good functional outcome at 3 months was defined as an mRS score of 0 to 2. Multivariable linear regression and multivariable logistic regression analyses were performed to examine the association between TMT and functional outcomes.
**Results:** Of the 141 patients screened, a total of 97 patients (mean age 73.8 ± 10.3; 47.4% male, NIHSS at admission 7 [interquartile range (IQR) 4–12]) was included in this analysis. TMT was measured at 5.8 [IQR 3.2–9.7] days prior to the initiation of comprehensive rehabilitation, and mean TMT of the patients was 5.46 ± 1.73 mm. At discharge, patients had an MBI of 48.0 ± 32.9. Among included patients, 47 (48.0%) had a good functional outcome at 3 months and patients with a good functional outcome had a thicker TMT compared to those with a poor functional outcome (5.94 ± 1.91 mm vs. 4.98 ± 1.39 mm, $p < 0.01$). In multivariable regression analysis adjusting for age, sex, NIHSS, body mass index, and recanalization therapy, thicker TMTs were associated with higher MBI scores at discharge ($\beta = 5.90$, $p < 0.01$), and were also associated with better functional outcome at 3 months (adjusted odds ratio 1.08 [95% confidence interval 1.01–1.14], $p = 0.02$).
**Conclusions:** TMT, a pragmatic surrogate marker of sarcopenia measured at the initiation of the comprehensive rehabilitation program, was associated with functional outcomes at discharge and at 3 months after ischemic stroke. Strategies to prevent muscle wasting during acute stroke care, including early rehabilitation, may help improve functional outcomes in patients with stroke.

*Intensive Care Medicine Experimental* 2024, **12 (suppl 1)**: 001537

**Introduction:** In-Hospital Cardiac arrest (IHCA) encompasses an area that are frequently encountered, with a better survival rate as compared to out-of-hospital cardiac arrest (OHCA). Nonetheless, they are associated with higher poor neurological outcomes. According to the ACLS guidelines which classify the causes of cardiac arrest as 5H/5 T, unlike broadly, the most common aetiology of OHCA is an acute coronary syndrome (cardiac cause), while the cause of IHCA is varied. The survival rate and neurological outcome of IHCA in Lower middle-income countries (LMIC) remains under-studied. Healthcare professionals in LMICs practicing in resource-limited settings have lower awareness and skills about ACLS as compared to their Western counterparts. This study was undertaken to study the incidence of IHCA and their outcomes in a tertiary-level hospital.
**Objectives:** To study the incidence and neurological outcome of patient's with IHCA admitted to our hospital. The primary outcome was survival at the time of discharge. The secondary outcome evaluated the percentage of patients who achieved a return of spontaneous circulation (ROSC) and the neurological outcome at the time of discharge.
**Methods:***Study Design*: a cross-sectional retrospective analysis. *Study period*: duration of two years. *Inclusion criteria:* Adult patients who were admitted to our hospital and were being managed in out-of-intensive care units. *Exclusion criteria:* Patients who had 'Do Not Resuscitate' Status and those admitted to the intensive care unit were excluded.*Data Collection:* The data was obtained from the code blue forms that were filled at the time of cardiac arrest in patients. The medical records were accessed to complete the missing data. Institutional ethics committee approval was taken and a consent waiver was given. *Statistics:* Data was analysed using descriptive statistics.
**Results:** The total number of cardiac arrests with completed code blue forms was filled for 101 patients. The average age and gender were 53 years and males respectively, at the time of arrest. The incidence of ROSC in the IHCA was found to be 60%. The most common rhythm that was recorded in the patients who achieved ROSC was pulseless electrical activity [PEA] (60%) followed by asystole in 16% of patients.

Non-shockable rhythm was more commonly recorded (86%) in patients with ROSC. The etiology most commonly associated with cardiac arrest in our study was hypoxia (59%). Almost 70% of the patients did not suffer from acute kidney injury after ROSC in IHCA. The survival rate of IHCA in our study was 18% with shockable rhythm having a better survival rate as compared to non-shockable rhythm and around 53% of the total survivors had a favourable neurological outcome at the time of discharge (Glasgow Coma Score > 12). A high percentage of 43% (44) of the total patients withdrew medical care due to the futility of medical care or inability to bear medical expenditure.
**Conclusions:** In this study, although an incidence of 18% IHCA was associated with a good neurological outcome in half the patients who achieved ROSC, the burden on healthcare remains high. Mandatory ACLS training of healthcare personnel can help to reduce IHCA and hence burden on healthcare.

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001538

**Introduction:** Pulmonary fibrosis, a serious sequela of ARDS, significantly reduces life expectancy and quality. However, the mechanisms driving fibrosis in ARDS still remain elusive. ARDS can result from direct causes like bacterial, Influenza, and SARS-CoV-2 pneumonia, or indirect causes like non-pulmonary sepsis. Especially across direct ARDS etiologies lung inflammation and injury significantly involve inflammasome caspase-1 signaling, with IL-1β and IL-18 production. Moreover, inflammasome caspase-1 signaling also fosters lung fibrosis in other inflammatory lung diseases. Thus, we hypothesized a central role of inflammasome caspase-1 signaling in the fibrotic response of direct ARDS.
**Methods:** Bronchoalveolar lavage fluid (BALF) was collected from indirect ($n = 11$), SARS-CoV-2 ($n = 78$), Influenza ($n = 12$), and bacterial ($n = 17$) ARDS patients at 2 ARDS centers. Fibrosis-associated mediators, inflammatory cytokines, and caspase-1 were analyzed by multiplex immunoassay and immunoblotting. BALF cells were incubated ex vivo with the caspase-1 inhibitors tetracycline or VX-765 and examined after 16 h. K18-hACE2 mice were infected with SARS-CoV-2. Cytokine production and fibrosis were analyzed after 8d in lungs and BALF.
**Results:** Influenza, SARS-CoV-2 and bacterial ARDS patients exhibited increased pulmonary levels of profibrotic matrix metalloproteinases (MMP)-1, -2, -7 and -12, fibrosis-associated mediators including CC-chemokine ligand (CCL) -18, plasminogen activator inhibitor type 1 (PAI-1) and Fibroblast growth factor compared to indirect ARDS patients ($p \leq 0.05$). Indicating caspase-1 orchestrated inflammation, elevated pulmonary IL-1β and IL-18 levels and increased caspase-1 activation were found in direct ARDS patients ($p \leq 0.05$). Strong correlations between IL-18 and MMP-1, -2 as well as PAI-1 ($r \geq 0.72$; $p \leq 0.001$) indicate a significant association between caspase-1-mediated inflammation and pulmonary fibrotic response in direct ARDS patients. Tetracycline and VX765 treatment in SARS-CoV-2 infected mice decreased caspase-1 activation as well as IL-1β and IL-18 production and associated lung damage ($p \leq 0.039$). Notably, caspase-1 inhibition further reduced pulmonary production of the profibrotic mediators MMP-2, -8, -9, -12, CCL-12, PAI-1, and S100A9 ($p \leq 0.05$) and histological analysis showed reduced pulmonary fibrosis. BALF cells from direct ARDS patients continued producing IL-1β and IL-18 and profibrotic mediators like MMP-2, PAI-1 and Procollagen I ex vivo. Tetracycline and VX-765 inhibited IL-1β and IL-18 production as well as caspase-1 activation ($p \leq 0.03$). Of note, tetracycline and VX-765 also dose-dependently decreased the production of MMP-2, PAI-I, and Procollagen I ($p \leq 0.05$).
**Conclusions:** Our study establishes a link between caspase-1 activation and pulmonary fibrotic response in patients with direct ARDS. Caspase-1 inhibition reduced the fibrotic response in both murine and human ex vivo studies. It should therefore be considered as a treatable trait for lung fibrosis in direct ARDS.

### Recommended dosages of analgesic and sedative drugs in intensive care result in a low incidence of potentially toxic blood concentrations

U. Lennborn[1], A. Johansson[2], E. Lindgren[1], E.I. Nielsen[3], H. Sandler[4], M. Bertilsson[5], R. Kronstrand[2], J. Ahlner[6], F.C. Kugelberg[6], S. Rubertsson[1]

**Correspondence:** U. Lennborn
***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001539

**Introduction:** Standard dosages of analgesic and sedative drugs are given to intensive care patients. It is not fully clear how best to determine dosage regimens of analgesics and sedatives in the clinical care of critically ill patients [1]. The resulting range of blood concentrations achieved with standard dosages administered to an ICU population can vary significantly between patients [2,3]. Historically, clinical studies have used plasma to determine drug concentrations, and therefore almost all reference values are from plasma [4]. In the field of postmortem toxicology, on the other hand, whole blood has been the sample material of choice. Plasma concentrations are not equivalent to whole blood concentrations [5].
**Objectives:** The purpose of this observational study was to describe daily dosages, measured blood concentrations and clinical responses in critically ill patients. The purpose was also to contribute to establishing whole blood concentration reference values of the drugs investigated.
**Methods:** A descriptive study of prospectively collected data from 302 admissions to a general intensive care unit (ICU) at a university hospital. We included all patients from age 16 and up. Ten drugs (clonidine,

fentanyl, morphine, dexmedetomidine, ketamine, ketobemidone, midazolam, paracetamol, propofol and thiopental) were investigated and daily dosages recorded. Blood samples were collected twice daily, and drug concentrations were measured. Clinical responses were registered using the Richmond agitation-sedation scale (RASS) and Visual analogue scale (NRS).
**Results:** Drug dosages were within the recommended dose ranges. Blood concentrations for all ten drugs showed a wide variation within the cohort, but only 3% (122 of 3827) were above the therapeutic interval. Clonidine (57 of 122) and midazolam (38 of 122) concentrations were the most common above therapeutic interval. RASS and NRS were not correlated to drug concentrations (Figs. 1 and 2).
**Conclusions:** Using recommended dose intervals for analgesic and sedative drugs in the ICU setting, combined with regular monitoring of clinical responses such as RASS and NRS lead to 97% of concentrations being below the upper limit in the therapeutic interval. This study contributes to whole blood drug concentration reference values regarding these ten drugs.

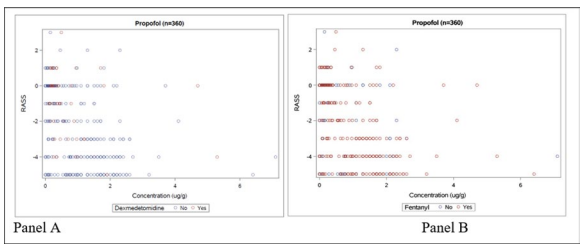

**Fig. 1 (abstract 0015394)** Propofol concentrations with corresponding RASS value within 4 h of sampling time. Panel A: with and without dexmedetomidine. Panel B: with and without fentanyl

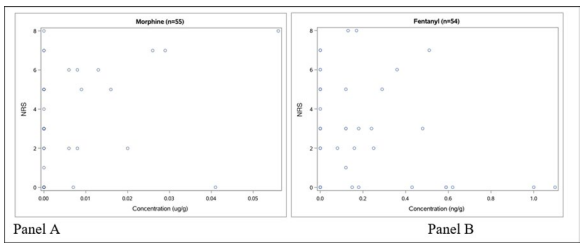

**Fig. 2 (abstract 001539)** Panel A: morphine concentrations with corresponding NRS value within 4 h of sampling time. Panel B: fentanyl concentrations with corresponding NRS value within 4 h of sampling time

**Introduction:** Post Intensive Care Syndrome (PICS) encompasses physical, cognitive, and mental health impairments that persist after the patient has been discharged from the Intensive Care Unit (ICU). The main factors related to the development of PICS are: duration of invasive mechanical ventilation (IMV) and ICU length of stay, severity of illness, age and pre-existing conditions, complications, degree of immobility, psychological stress and rehabilitation treatment.
**Objectives:** To characterize the population who developed PICS and identify the most important risk factors for the development of PICS in patients admitted for at least 3 days in the ICU.
**Methods:** All patients admitted for at least 3 days in the ICU between January and June of 2023 were evaluated approximately 3 months after ICU discharge by our follow-up team.
Patients who died before the consultation or who didn't show for the consultation were excluded from this analysis.
PICS and quality of life were determined based on clinical evaluation and through the application of several scales such as Hospital Anxiety and Depression Scale, Post-Traumatic Syndrome Scale-14, Minimental State Examination, Frailty Scale, Functional Independence Measure and EQ-5D.
The variables used in this analysis for the characterization of the population were age, gender, ICU and hospital length of stay, Frailty Scale, EQ-5D, IMV and delirium.
We calculated the odds ratio and $p$-value (considering $p$-value < 0.05 for positive hypothesis) for PICS considering IMV, delirium and length of ICU stay 7 or more days.
**Results:** Our population consisted of 117 patients, 32.5% of whom were females, the average age was 66.1 years old, the average ICU length of stay was 7.8 days, and the average hospital length of stay was 26.7 days.
The average initial Frailty Scale was 2.34, and at follow-up was 3.25. The average quantification of the quality of life according to the EQ-5D questionnaire was 65%.
Thirty-three patients (28.2%) were invasively ventilated. Delirium was identified in 45 patients (38.5%). PICS was present in 42 patients (35.9%).
Among patients that presented PICS, 22 of them were invasively ventilated (52.4%), 23 had delirium (54.7%), the ICU average length of stay was 10.3 days and the average hospital length of stay was 34.9 days. The average age was 65.5 in the PICS group and 28.6% were females.
The odds ratio for PICS and IMV was 6.4 and the $p$-value < 0.0001. The odds ratio for PICS and delirium was 2.9 and the $p$-value < 0.0075. Considering a length of stay of 7 or more days the odds ratio was 2.3 and the $p$-value < 0.032.
**Conclusions:** The risk of PICS is higher for invasively ventilated patients, for those who developed delirium and for those with an ICU length of stay of 7 or more days.
There was an increase on Frailty Scale after the ICU stay.
To reduce PICS and/or intervene sooner in this patient's recovery, risk factors should be taken into account.

### Effects of artificially-induced iPEEP and post-inspiratory pause on dead space and slope of capnographic phase III in acute respiratory failure

C. Zilianti[1], A. Kyriakoudi[2], E. Potamianou[2], C. Karakatsanis[2], K. Pontikis[2], A. Koutsoukou[2], M. Pecchiari[1]

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001542

**Introduction:** According to a previous report (Brandolese et al., 1993), artificially induced intrinsic positive end-expiratory pressure (iPEEP) causes a deterioration of gas exchange in mechanically ventilated patients with acute respiratory failure, presumably because of a less homogeneous distribution of inspired gas.
**Objectives:** This hypothesis was investigated indirectly by measuring the slope of phase III, anatomic and physiologic dead space using volumetric capnography.
**Methods:** Measurements were obtained in 11 sedated, mechanically ventilated paralyzed acute respiratory failure patients with iPEEP < 3 cmH2O assessed at zero end-expiratory pressure, and without a known diagnosis of chronic obstructive pulmonary disease. In all experimental conditions, respiratory rate, ventilation and total PEEP (PEEPtot) were the same, but the same PEEPtot was obtained either by applying external PEEP (ePEEP condition) or by shortening the duration of expiration to produce iPEEP. iPEEP was induced either by reducing the inspiratory flow (Fins) and increasing the duration of the inflation (TI) (iPEEP with long TI, iPEEPlongTI condition), or by keeping constant Fins and TI, and introducing a long post-inspiratory pause (pIp) (iPEEP with a long pause, iPEEPlongP condition).
**Results:** PEEPtot was not significantly different in the three experimental conditions (6.6 ± 1.3, 6.4 ± 1.5 and 6.4 ± 1.2 cmH2O, $P = 0.474$, for ePEEP, iPEEPlongTI and iPEEPlongP, respectively), as was the corresponding end-expiratory volume above equilibrium volume, measured during deflation to ZEEP ($P = 0.158$). iPEEP was not different between iPEEPlongTI and iPEEPlongP (4.9 ± 1.1 and 5.1 ± 0.9 cmH2O, $P = 0.453$, respectively), but substantially greater than in the ePEEP condition (0.6 ± 0.3 cmH2O, $P < 0.001$). PaO2 was not significantly different among the three conditions ($P = 0.262$), while PaCO2 was lower at iPEEPlongP (35.2 ± 4.7 mmHg) than at ePEEP (38.4 ± 5.2 mmHg, $P < 0.001$) and iPEEPlongTI (38.3 ± 4.2 mmHg, $P = 0.019$). Relative to ePEEP, slope of phase III, anatomic, physiologic and alveolar dead space were not different at iPEEPlongTI (Δ − 0.7 ± 1.8%CO2/L, $P = 0.655$; 1 ± 7 ml, $P = 1.000$, 2 ± 22, $P = 1.000$ and 1 ± 17 ml, $P = 1.000$, respectively). In contrast, the same parameters were significantly lower at iPEEPlongP (Δ − 1.6 ± 1.1%CO2/L, $P < 0.002$, − 18 ± 9 ml, $P < 0.001$, − 32 ± 19 ml, $P < 0.001$, and − 14 ± 13 ml, $P = 0.017$, respectively).
**Conclusions:** In these patients, no difference in slope of phase III, anatomic and physiologic dead space were detected between ePEEP and iPEEPlongTI, suggesting that during iPEEPlongTI the effect of iPEEP-induced alterations of ventilation distribution, if any, were completely compensated by the increase of inspiratory duration (Åström et al., 2008). In contrast, the prolongation of pIp led to a significant reduction of heterogeneity as indexed by the slope of phase III in the iPEEPlongP condition, despite the presence of iPEEP.

**Introduction:** Healthcare-associated ventriculitis or meningitis (HCVM) is a difficult-to-distinguish infection in neurocritical care. Conventional cerebrospinal fluid (CSF) parameters and classical microbiology are the mainstay for establishing diagnosis, while various factors decrease their diagnostic value. Recent guidelines propose using CSF lactate and procalcitonin (PCT), but their diagnostic value remains controversial.
**Objectives:** To evaluate and compare the performance of lactate and PCT in HCVM diagnosis.
**Methods:** This prospective observational study was conducted from January 2019 to March 2024. We enrolled all consecutive adult patients with suspected HCVM after neurosurgical procedures. We excluded patients with recent intracranial infection, immunocompromised, and pregnant women. The diagnosis of HCVM was based on the definition of the IDSA guidelines 2017. Demographics, indications for neurosurgical procedures, and the following blood and CSF parameters for each patient were recorded: white blood cell count (WBC), protein content, glucose, lactate, and PCT as well. Blood and CSF samples collected from an EVD were analyzed at the same time. Patients were allocated into two groups (group 1 = HCVM/group 2 = non-HCVM). Chi-square, Student's $t$, and Mann-Witney $U$ test were used as appropriate. The $p$-value was set at 0.05. ROC curves were constructed, and the best cut-off points were determined. Statistical analyses were performed using R statistical software.
**Results:** A total of 60 patients were included, predominantly males (55%), with a median age of 60 (IQR:50–67). The main reasons for ICU admission were ruptured aneurysm and intracerebral hemorrhage (43,3%). HCVM was diagnosed in twenty patients (33,3%), with the majority of pathogens being Gram-negative bacteria (Acinetobacter baumannii 47,6%, Klebsiella pneumoniae 33,3%, Enterobacter aerogenes 4,8%). Age and gender did not significantly differ between the two groups ($p > 0.05$). The differences in CSF glucose, CSF/Serum glucose, CSF PCT, CSF lactate, CSF/Serum Lactate, CSF WBC, and CSF albumin between the groups were statistically significant ($p < 0.05$). There was no association between CSF/Serum PCT and HCVM in our cohort ($p = 0.113$). Based on the ROC curves, the CSF lactate measurement had the best diagnostic accuracy for HCVM (AUC: 0,936, 95%CI: 0.841 to 0.983) with a cut-off point > 4.4. The AUC values for CSF glucose, CSF/Serum glucose, CSF/Serum lactate, CSF PCT, CSF WBC, and CSF albumin were 0,786, 0,819, 0,809, 0,834, 0,769, and 0,715, respectively. Hence, CSF lactate is classified as an excellent test, CSF/Serum lactate, CSF/Serum glucose, and CSF PCT as a good test, while CSF glucose, CSF WBC, and CSF albumin are classified as fair tests.
**Conclusions:** Based on our findings, all parameters measured except CSF/Serum PCT showed a significant correlation with the HCVM diagnosis. Among the assessed biomarkers, CSF lactate had the best predictive performance. Our results extend knowledge and shed light upon the diagnostic dilemma of HCVM.

**Introduction:** Bacteremias from Acinetobacter baumannii (A. baumannii) are associated with high mortality in critically ill patients.
**Objectives:** We pursued to investigate risk factors for mortality-related A. baumannii bacteremia.
**Methods:** Retrospective, single-center study of critically ill patients with A. baumannii bacteremia during a period of a four-year period Patients were divided in two groups according to their 28-day mortality related to A. baumannii. Mortality related to A. baumannii was defined as the patient dying from septic shock caused by the A. baumannii bacteremia.
**Results:** Overall, 120 patients were analyzed, and 28-day mortality related to A. baumannii was 49.2% (59/120). Patients were divided into two subgroups. There was no difference in baseline characteristics between the two groups. Patients that died from A. baumannii had worse 7 day outcomes: lower rate of microbiological cure or resolution of sepsis and lower rate of being off vasopressors. Multivariate logistic regression analysis showed that intravenous colistin was associated with increased survival (OR 0.170, 95%CI 0,034–0.847) while sepsis (OR 19.994, 95%CI 1.40–285.552) and septic shock (OR, 25.556, 95%CI 2.618–269.334) were risk factors for mortality. Multivariate regression analysis performed only in colistin-resistant A. baumannii cases showed a similar survival benefit for iv colistin treatment ( OR 0.020, 95%CI 0.001–0.339).
**Conclusions:** Intravenous colistin treatment appears to offer a survival benefit in critically ill patients with A. baumannii bacteremia. This benefit persists among patients with colistin-resistant strains.

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001545

**Introduction:** Sepsis-induced cardiomyopathy (SIC) is a well-recognized complication of sepsis, however, its underlying mechanisms are complex and incompletely understood. In a rat sepsis model, we have shown that SIC is accompanied by a fall in cardiomyocyte membrane cholesterol. Given the critical role of membrane cholesterol for adrenergic signalling and contractility, this may be a key mechanism. An in vitro model can aid mechanistic studies and the identification of potential therapeutic interventions. We therefore established a cellular model using an H9C2 rat cardiomyocyte cell line that recapitulates the sepsis-induced cholesterol decrease in cardiomyocytes. This model utilises the chemical depletion of membrane cholesterol by methyl-ß-cyclodextrin (MßCD). The current study investigates whether different cholesterol formulations (modified cholesterols and specific carriers) can restore membrane levels.
**Objectives:** To test the ability of different cholesterol formulations to replenish plasma membrane cholesterol after chemical depletion in a rat cardiomyocyte cell line.
**Methods:** Cells were incubated with 5 mM methyl-ß-cyclodextrin (MßCD) for 30 min and treated with 25, 75 or 125 mM of three different liposomal cholesterol solutions for 1 h. Cell cholesterol concentration was measured by enzymatic Amplex Red assay and normalised to protein, measured by BCA assay. *p*-values were calculated using one-way ANOVA with multiple comparisons (PRISM Version 9.5.1). Data are presented as mean ± SD. Groups were considered statistically different if $p$ values $< 0.05$.
**Results:** Significant variation was seen in the ability of the different liposomal formulations to elevate cholesterol levels in cholesterol-depleted H9C2 cells. The Lip7 formulation was ineffective at all doses tested. The Lip39 formulation restored cell [cholesterol] to normal levels but was dose-independent. The Lip40 formulation, however, achieved supranormal levels even at the lowest dose (25 mM cholesterol), and this increased further with increased dose (Fig. 1).
**Conclusions:** The ability of liposomal formulations to restore depleted cholesterol levels in cardiomyocytes depends on their composition. Further investigations are needed to explore the therapeutic potential of such formulations in sepsis-induced cardiomyopathy.

### Intravenous N-acetylcysteine versus intravenous theophylline in the prevention of contrast-induced nephropathy in critically ill patients

R. Banoub[1]
[1]Anesthesia and Critical Care, Cleveland Clinic Abu Dhabi, Abu Dhabi, United Arab Emirates
**Correspondence:** R. Banoub
***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001546

**Introduction:** Contrast-induced nephropathy (CIN) is defined as an acute deterioration in renal function after exposure to, and as a result of, contrast media (CM) [1]. However, acute renal failure (ARF) occurring after procedures associated with contrast administration may be caused by several different factors including volume depletion, atheroembolic disease, and congestive heart failure. Because it is not always possible to clinically differentiate the cause of the renal dysfunction, it may be more appropriate to term this condition ascontrast-associated nephropathy [2].
**Objectives:** Despite the use of several agents for prophylactic agents, contrast-inducednephropathy (CIN) remains a crucial clinical problem. The aim was to compare the efficacy of intravenous N-acetylcysteine (NAC) and intravenous theophylline in the prevention of CIN in critically ill patients.
**Methods:** A total of 90 patients were admitted to the ICU with at least one risk factor for CIN and randomly divided into three groups. All patients received the regular management of renal protection with good hydration, to maintain adequate intravenous volume expansion with isotonic crystalloids (normal saline: 1–1.5 ml/kg/h) 3–12 h before the procedure, and it was continued for 6–24 h afterward. In the first group, patients received 6 mg of theophylline intravenously over 30 min as a loading dose, followed by a maintenance dose of 0.5 mg/kg/h intravenously, to be started after the loading dose (group T). In the second group, patients received the full course of treatment with NAC (group A), which comprised three consecutive intravenous infusions: first infusion as an initial loading dose of 150 mg/kg body weight infused in 200 ml over 1 h, followed by the second infusion of 50 mg/kg in 500 ml over the next 4 h, followed by the third infusion of 100 mg/kg in 1 l over the next 16 h (to be completed on the day of the examination). Control group: in this group, 30 patients received no additional drug before the administration of radio contrast medium. They only received the regular management of renal protection with good hydratio.
**Results:** Despite the inclusion of ICU patients at high risk for CIN, we found a significant lower incidence of CIN and a lower incidence of patients requiring dialysis among patients under prophylaxis of intravenous NAC and intravenous aminophylline, as creatinine concentration was elevated by 25% in only four patients in the NAC group and only in three patients in the aminophylline group, and the incidence of CIN and patients requiring dialysis were significantly lower ($P < 0.045$) than that in the control.
**Conclusions:** We concluded that the administration of intravenous NAC or intravenous theophylline around the time of contrast administration prevents renal injury inequal efficacy compared with patients receiving no additional drugs at the time of contrast administration as regards incidence of nephropathy and incidence of dialysis among study patients.

### Presepsin as a valuable prognostic biomarker of severe sepsis and predictor of outcome

S. Papoti[1], G. Gkogkos[1], E. Lazoudi[1], G. Katsikaki[1], E. Kerezidou[1], D. Ntantos[1], S. Mylonas[1], C. Iasonidou[1]
[1]B ICU, General Hospital "G. Papanikolaou", Thessaloniki, Greece
**Correspondence:** S. Papoti
***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001547

**Introduction:** Sepsis is one of the leading causes of morbidity and mortality worldwide. Early and accurate diagnosis is crucial. Procalcitonin (PCT), is widely reported as a useful biomarker for the diagnosis of septic patients and a reliable predictor of mortality. Presepsin (sCD14-ST) is supported to be a novel sepsis biomarker and a good prognostic indicator. High levels seem to be associated with a worse prognosis and a more complicated clinical course. Presepsin may be valuable when used in association with other commonly used prognostic evaluators to better identify patients at risk of severe infection.
**Objectives:** We aimed to evaluate Presepsin in ICU septic patients with abnormal PCT and high SOFA score (Sequential Organ Failure Assessment score) and correlate them with sepsis severity and outcome.
**Methods:** Adult ICU patients treated for suspected or confirmed bacterial infection were studied retrospectively, over one year period. PCT and Presepsin levels were evaluated at the onset of the infection. PCT > 2 ng/mL and Presepsin > 1000 pg/mL were defined as cutoff values of severe sepsis and septic shock (according to Sepsis-3 definitions) and were correlated with SOFA score > 10 and mortality.
**Results:** In our study, 89 septic patients were included, 28 females and 61 males with a median age of 61 years (range 18–83 years) and a median ICU LOS of 16 days (range 5–93 days). The mortality rate for the total of the included patients was 40.4%, out of which 3/4 (77,36%) due to septic shock. 40 (44.9%) patients were diagnosed with severe sepsis or septic shock. High levels of PCT and Presepsin were associated with septic shock (66.7% and 69.4%, respectively) and mortality (66.7% and 63.3%, respectively), which was statistically significant ($p < 0.05$). Clinical assessment of SOFA score > 10 was also associated with septic shock and mortality (85.7% and 71.4%, respectively), ($p < 0.05$). Further statistical analysis showed that Presepsin > 1000 is positively associated with the diagnosis of septic shock (OR = 12.84, $p < 0.01$). Multivariable analysis showed that Presepsin > 1000 and SOFA > 10 were independent variables strongly correlated to septic shock, whereas PCT > 2 did not show statistical significance when adjusted for the other two variables.
**Conclusions:** According to our study, Presepsin is a valuable prognostic biomarker that can evaluate the severity of sepsis. Moreover, high levels are associated with more unfavorable outcomes. Correlation with other commonly used markers, such as SOFA score and PCT, may further determine the severity of the infection and the outcome.

### The outcome of high-frequency oscillatory ventilation in pediatric patients with acute respiratory distress syndrome in an intensive care unit

T. Alayed[1]
[1]Critical Care Medicine Department, King Faisal Specialist Hospital & Research Centre, Riyadh, Saudi Arabia
**Correspondence:** T. Alayed
***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001548

**Introduction:** In adults with acute respiratory distress syndrome (ARDS), high-frequency oscillatory ventilation (HFOV) has been associated with higher mortality rates. Therefore, its use in children with ARDS is still controversial.
**Objectives:** Evaluate the overall mortality of HFOV in children with ARDS and explore mortality-related risk factors; compare the outcome of using HFOV post-endotracheal intubation early ($\leq$ 24 h) versus late ($\leq$ 24 h).
**Methods:** Retrospective chart review of all pediatric patients with ARDS aged one week to 14 years, who were admitted to the Pediatric Intensive Care Unit (PICU) at the King Faisal Specialist Hospital and Research Centre in Riyadh, Saudi Arabia, from January 2016 to June 2019 and who required HFOV. Data were analyzed using STATA software.
**Results:** 135 ARDS patients including 74 females (54.8%), and 61 males (45.2%), with a median age (interquartile range) of 35 (72) months. The overall mortality rate was 60.0% (81/135), and most died in the first 28 days in the PICU (91.3%, 74/8). Of non-survivors, 75.3% (61/81) were immunocompromised, and 24.7% (20/81) were immunocompetent patients, 52 (64.2%) received inotropic support, 40 (49.4%) had a bone-marrow transplant (BMT) before HFOV initiation. Although the prone position was used in 20.7% (28/135) to improve the survival rate post-HFOV ventilation, only 28.6% (8/28) survived. In addition, altered code status or chemotherapy reported a significant association with mortality ($P < 0.05$). Interestingly, early HFOV initiation ($\leq$ 24 h) did not seem to have a high impact on survival compared to late initiation (> 24 h); (57.4% vs. 42.6%, $P = 0.721$).
**Conclusions:** Immunocompromised and oncology patients, including post-BMT, reported poorer outcomes, and neither the prone position nor early use of HFOV improved outcomes. However, it is recommended to replicate the study in a larger cohort to generalize the results.

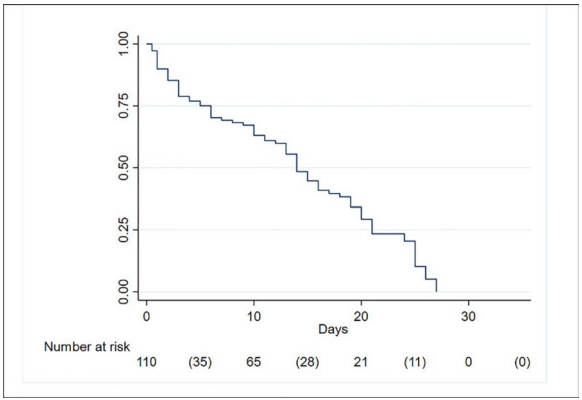

**Fig. 1 (abstract 001548)** Kaplan–Meier curve of patients who expired within 28 days of the PICU stay. The number in parentheses represents the number of deaths for each time period

**Introduction:** Transplant recipients commonly harbor multidrug-resistant organisms (MDROs), as a result of frequent hospital admissions and increased exposure to antimicrobials and invasive procedures.
**Objectives:** We investigated the impact of patient demographic and clinical characteristics on MDRO acquisition, and the impact of MDRO acquisition on ICU & hospital length of stay, and on ICU and 1-year mortality post heart transplantation (HT).
**Methods:** This retrospective study analyzed 98 consecutive HT patients over a ten-year period (2013–2022) in a single transplantation center. Data was collected regarding MDROs commonly encountered in critical care.
**Results:** In 98 patients (70% male) *Acinetobacter baumannii* (14.3%), *Pseudomonas aeruginosa* (12.2%) and *Klebsiella pneumoniae* (11.2%) prevailed. Compared to MDRO-free patients, the MDRO group had significantly greater BMI ($p=0.002$), higher rates of renal failure ($p=0.017$), primary graft dysfunction (10% vs 4.5%, $p=0.001$), surgical re-exploration (34% vs 14%, $p=0.017$), mechanical circulatory support ( 47% vs 26% $p=0.037$) and renal replacement therapy (28% vs 9%, $p=0.014$), as well as longer extracorporeal circulation time (median 210 vs 161 min, $p=0.003$). Median ICU and hospital stay were prolonged (15.5 vs 9 days, $p=0.001$ and 38 vs 28 days, $p=0.006$, respectively) compared to the MDRO-free group, while 1-year mortality was higher (28% vs 7.6%, log-rank- × 2: 7.34).
**Conclusions:** Following heart transplantation, a predominance of Gram-negative MDROs was noted (south-eastern Europe pathogen resistance pattern). MDRO acquisition was associated with higher complication rates, prolonged ICU and total hospital stay, and higher late post-transplantation mortality.

**Introduction:** The increased genetic load allowing antibiotic resistance may also translate into a reduction of the virulence of bacteria, a phenomenon named loss of fitness. This rationale was contested and is not so easily applied to the immunosuppressed patient. The kinetics of the infection are determined by factors from both the infectant and host. If the influence of the host is reduced then the microorganisms' is decisive.
**Objectives:** This study aims to determine the relationship between resistance profile and infected critical hematological patients.
**Methods:** Retrospective cohort with 89 patients with hematologic malignancies who were admitted to an ICU from January 2016 to August 2023 with bacterial infection. They were divided into 2 groups: group 0 with a low resistance profile (sensitive to amoxicillin-clavulanic acid) and group 1, which included those with more significant resistance patterns (resistant to amoxicillin-clavulanic acid). The latter was subdivided into intermediate resistance (group 3: sensitive to piperacilin-tazobactam); ESBL positive and Carbapenemase positive (group 4). The population was characterized by their baseline characteristics, hematological cancer, their profile of resistance, organ failure scores and ICU e in-hospital mortality.
**Results:** There were 89 patients presented with infection at admission. Median age was 61 years. The most prevalent hematologic malignancy was acute myeloid leukemia (44.9%), non-hodgkin's lymphoma (13.2%) and multiple myeloma (10.1%). Median ICU and in-hospital mortality was 69.2% and 79.4%. The most common infection was pneumonia (63%), followed by spontaneous bacteriemia (24%) and neutropenic colitis (8%).
Hospital mortality was similar between patients with infection agent isolation vs those without microorganism isolation (77.4% vs 73.1%, *p*-value 0.624).
When analyzing the severity scores we found that the median sofa 48h before admission was similar between groups 0 and 1 (5 vs 5, $p=0.120$), 24h before admission was higher in group 1 (6 vs 5, $p=0.026$). At admission, the scores were similar (SOFA 8 vs 10, $p=0.184$; APACHE 16 vs 18, $p=0.396$; SAPS II 57 vs 60, $p=0.704$). Hospital mortality between these two groups was similar (75% vs 75.8%, *p*-value 0.624).
When subdividing in the type of resistance, we found that the four study groups were similar in terms of SOFA score 48h before admission (group 0: score 5; group 1: score 5; group 2: score 6; group 3: score 5, *p*-value 0.420) and at admission (group 0: score 12, group1: score 11, group 2: score 13; group 3: score 10, *p*-value 0.135). Apache at admission was also similar (group 0: score 17, group1: score 21, group 2: score 18; group 3: score 17, *p*-value 0.414) as well as the SAPS II ( (group 0: score 54, group1: score 60, group 2: score 55; group 3: score 58, *p*-value 0.713). Hospital mortality was similar (group 0: 81%, group 1: 69%, group 2: 75%; group 3: 70%, *p*-value 0.980).
**Conclusions:** There is a complex interplay of forces in the infection in the critical hematological patient. The loss of fitness in more resistant microorganisms doesn't seem to be predominant in this type of immunosuppression. It may point that the characteristics of the host are more determinant.

**Introduction:** Spontaneous intracerebral hemorrhage (ICH) is a common neurological emergency that is associated with high rates of disability and mortality, and is a frequent reason for admission to Intensive Care Units (ICU).
**Objectives:** The purpose of this study was to identify risk factors related to mortality in patients with spontaneous intracerebral hemorrhage admitted to Intensive Care Units.
**Methods:** Retrospective, observational, study performed on patients with ICH admitted to the ICU of H.G.*U* Gregorio Marañón (Madrid, Spain), between 2022 and 2023 years. Epidemiological data, ICH risk factors, comorbidities, severity scores (APACHE II, GCS and ICH score), hemorrhage characteristics (location, volume, intraventricular involvement (IVH) and midline displacement), patient clinical characteristics, organic support and outcome were collected during ICU stay.
Descriptive data were expressed as means with standard deviation for normally distributed continuous variables, medians with interquartile range (IQR) for non-normally distributed variables, and percentages for categorical data. The continuous variables were categorised according to the maximum discrimination point by the AUROC. A univariate and multivariate analysis was performed using logistic regression to determine the factors related to mortality.
**Results:** Eigthy-nine patients, 63% male. Age 62 yrs (51–72). Charlson Comorbidity Index 0 pts (0–2). Severity scores: APACHE II 22 pts (16–26), ICHS 3 pts (2–4), GCS 10 pts (5–14). Neutrophil-to-lymphocyte ratio 5 (3–11). Hemorrhage characteristics: brainstem location 14.6%, hematoma volume 36 cc (15–80), midline displacement 57% and IVH 66%. 25% of patients received surgical treatment (hematoma evacuation and/or decompressive cranectomy). During ICU stay, 85% of patients needed mechanical ventilation and 80% presented some complication. Overall mortality was 55%.
The results of the univariate analysis were: Age > 70 yrs (OR 3.59; CI 95% 1.27–10.16), Charlson Index > 2 pts (OR 4.83; 95% CI 1.61–14.45), GCS > 9 pts (OR 0.22; 95% CI 0.08–0.53), APACHE > 24 pts (OR 7.42; 95% CI 2.62–21.11), Neutrophil-to-lymphocyte ratio (OR 1.08; 95% CI 1.01–1.16), brainstem location (OR 6.50; 95% CI 0.76–55.25), hematoma volume (10cc) (OR 1.21; 95% CI 1.07–1.37), midline displacement (OR 2.52; 95% IC 1.06–5.97), IVH (OR 3.13; 95% CI 1.25–7.79), surgical treatment (OR 0.28; 95% CI 0.10–0.77), complication ICU stay (OR 1.71; 95% CI 0.60–4.84) and mechanical ventilation (OR 8.91; 95% CI 1.84–43.108).
In the multivariate analysis, on a maximum model including the previously described, the Charlson Index > 2 pts (OR 11.44; 95% CI 1.56–83.74), brainstem location (OR 51.56; IC 95% 1.28–2073.92), hematoma volume (10cc) (OR 1.32; IC 95% 1.03–1.69), mechanical ventilation (OR 17.48; IC 95% 1.02–299.33) and neutrophil-to-lymphocyte ratio (OR 1.10; IC 95% 1.01–1.21), were the factors independently associated with mortality.
**Conclusions:** In our experience, the factors independently related to mortality in patients with spontaneous intracerebral hemorrhage were the presence of comorbidities, hemorrhage location, hematoma volume, neutrophil-to-lymphocyte ratio and need for mechanical ventilation.

*Intensive Care Medicine Experimental* 2024, **12 (suppl 1)**: 001553

**Introduction:** ECMO is a cardiopulmonary support system used to assist patients with cardiovascular and/or respiratory failure. AKI has been reported to be one of the most common complications in patients receiving extracorporeal membrane oxygenation and is strongly associated with high mortality rates.
**Objectives:** To assess the incidence of AKI and AKI that requires renal replacement therapy (AKI-RRT) as well as mortality rates, in patients treated with VA ECMO in a single-center study.
**Methods:** Patients admitted consecutively to the Cardiac thoracic ICU of a Cardiac Surgery Center from January 2015 until June 2023 were retrospectively studied. The clinical data, duration and mode of ECMO, details of inotropic support, mode of RRT and length of stay in the ICU and the ward, were recorded. AKI was defined as per KDIGO criteria.
**Results:** The study included 108 patients, with a mean age of 59 (42–69) years; 59 (55%) were males. All patients recorded were supported with VA ECMO due to cardiogenic shock, 87 of them (81%) following cardiac surgery. Forty-eight patients underwent central VA ECMO. Eighty-two patients (76%) on ECMO died either in the ICU or in the ward; 55 out of them (67%) were complicated with AKI during hospitalization.
**Conclusions:** AKI occurs frequently in patients supported with VA ECMO and is associated with poor outcomes.

### Fostering teamwork for resilient staff and safe care in ICU: a multi-site ethnographic study (FEARLESS ICU)

A. Xyrichis[1], B. Wenning[2], S. Costello[2]
[1]London, United Kingdom, [2]Nursing, Midwifery, & Palliative Care, King's College London, London, United Kingdom
**Correspondence:** A. Xyrichis
*Intensive Care Medicine Experimental* 2024, **12 (suppl 1)**: 001555

**Introduction:** Teamwork in healthcare has long been linked with improved outcomes for staff (wellbeing), organisations (staff retention), and patients (safety). However, teamwork within the UK NHS remains problematic with negative consequences for patients and staff. Alarmingly, the recent NHS Staff survey shows a national decline in teamwork; with unexplained disparities across professions.
The post-pandemic landscape reflects significant pressures on clinical teams, especially in intensive care units (ICUs), with demands for more flexible and cross-boundary working in ad hoc teams with redeployed staff and new role developments. Early data show a negative impact on staff, with a lack of clarity on new ways of working, leading to stress, turnover, and patient safety concerns. The lasting consequences of the nature and shape of teamwork in ICUs post the pandemic remain unknown. This hinders efforts to strengthen clinical and system resilience.
**Objectives:** A) Examine the changing nature of teamwork in ICUs post-pandemic; B) Refine current teamwork frameworks given the changing context; and, C) Co-develop with staff a toolkit for strengthening ICU teamwork capacity moving forward.
**Methods:** Multi-method study over four stages. Stage 1: high-quality quantitative and qualitative evidence syntheses; and statistical analysis of the NHS Staff survey. The evidence syntheses will follow best practice guidance for publication in the Cochrane Library. Survey analysis to examine factors influencing teamwork utilising regression and modelling. Stage 2: fieldwork in five purposively selected (size, geography) ICUs, including non-participant observation, semi-structured interviews, and document analysis. Fieldnotes will be kept in a digital journal and interviews recorded and transcribed. Analysis will follow standard ethnographic principles of thematic coding, categorisation, and abstraction. Stage 3: reflexive workshops with staff and

toolkit development. To utilise design approaches and tools, such as quality circles, brainstorming, voting and creative conversations. Stage 4: dissemination and networking to identify potential sites for a future cluster-randomised trial, for which a protocol will be developed during the study in readiness for a successive funding application.
**Results:** Exploratory and confirmatory factor analysis of the NHS staff survey teamwork scale alongside inferential and descriptive statistics on teamwork, staff engagements, and burnout. Initial findings from the in-person fieldwork in two ICUs.
**Conclusions:** Project outputs will be disseminated widely through videos, blogs, a project website and newsletter; as well as policy briefs, news pieces, conference presentations and academic publications; and, a final project multistakeholder symposium bringing together clinicians, service users and policymakers. By generating an in-depth, evidence-based understanding of teamwork in ICU, and offering a toolkit to ICU teams across the NHS, the project can have a direct impact on the teamwork practice of ICU staff, improvement of which has long been linked with a better patient, staff and organisational outcomes.

### Both essential and nonessential amino acids in nutrition are needed to attenuate post-sepsis muscle fatigue and stimulate activity in a new pig model of ICU-acquired muscle weakness (ICU-AW)

N. Deutz[1], G. Ten_have,[2], P. Nghiem,[3], M. Mackey,[2], S. Rice[2], M. Engelen[2]
[1]KNSM, Texas A&M University, College Station, United States of America, [2]CTRAL, Texas A&M University, College Station, United States of America, [3]Veterinary Integrative Biosciences, Texas A&M University, College Station, United States of America
**Correspondence:** N. Deutz
***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001559

**Introduction:** Sepsis leads to long-term muscle weakness, fatigue, and reduced physical activity (ICU-AW). We developed an acute sepsis-recovery ICU-AW pig model to study whether meals with only essential (EAA) or all amino acids (TAA) improve ICU-AW symptoms.
**Methods:** In 49 pigs (±25 kg), sepsis was induced by i.v. live *Pseudomonas Aeruginosa* bacteria (5*10e8 CFU/hour). At $t=9$ h, recovery was initiated with i.v. gentamicin. Post sepsis, twice daily food was provided starting at 25% at Day 1 to 100% during Day 4–7. The 100% meals contained per kg BW: 15.4 gr CHO and 3.47 gr fat per kg BW, and a balanced free TAA (reflecting muscle) or EAA mixture (0.56 gr N: EAA or TAA group). We measured involuntary, isometric pelvic limb muscle strength and activity prior to and at Day 4–7 post sepsis. Peak force and downslopes of the fatigue curves were obtained from tetanus stimulations of the tibiotarsal muscles. Daytime homecage activity was video-tracked with Ethovision XT17 software (Noldus) and a unified score for weakness was used. Postabsorptive plasma amino acid (AA) concentrations by LC–MS/MS and two-way RM-ANOVA (time (sepsis recovery), intervention (nutrition), and interaction) ($\alpha=0.05$).
**Results:** Body weight reduction was found after sepsis in both groups, which was restored on Day 7 post-sepsis. Muscle Flexion. Strength: no ($p>0.2$) time, intervention or interaction effects. Fatigue increased over time ($p=0.0008$) and more in the EAA group ($p=0.0045$). TAA group had 30% less fatigue on Day 7 ($p<0.0001$) whereas the EAA group had more fatigue on Day3 and 7 ($p<0.0002$). Activity: General activity, maximum gait speed, and acceleration to start walking decreased below baseline in both groups at Day 6 post sepsis ($p<0.01$, all groups). Interactions with cage enrichments decrease over time in comparison with Day 2 (time effect: $p<0.0001$). The overall weakness score was lower in the TAA group vs EAA group ($p=0.031$), especially on Day 4–5 ($p=0.0461$, $p=0.0024$).
**Plasma** EAA changes were related to meal AA composition, whereas in response to the TAA meal, the plasma non-essential AA (NEAA) ARG ($p<0.0001$) and CIT ($p=0.0009$) were higher, and GLN ($p<0.0001$), GLU ($p<0.0001$) and TAU ($p<0.0001$) lower. In the EAA group, lower ARG ($p=0.0095$) and TAU ($p=0.0021$; more in EAA: $p<0.0001$), unchanged GLN ($p=0.97$) and increased CIT ($p<0.0001$; more in EAA: $p<0.0008$) were found. Tau-methylhistidine, a product of myofibrillar protein breakdown, increased by 56% in the EAA group (Day 3&7; $p<0.004$).
**Conclusions:** We conclude that providing an incremental TAA meal (EAA + NEAA) to our innovative sepsis-recovery pig ICU-AW model attenuates muscle fatigue and improves homecage physical activity more than the EAA meal and possibly reduces protein breakdown. We hypothesize that providing certain NEAA with EAA may play a key role in attenuating ICU-AW.

### The ketone body β-hydroxybutyrate reduces endothelial dysfunction following inflammatory activation

M.B. Müller[1], A. Schmid[1], M. Hübner[1], S. Hirschberger[1], S. Kreth[1]
[1]Department of Anesthesiology, University Hospital, LMU Munich, München, Germany
**Correspondence:** M.B. Müller
***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001560

**Introduction:** The postoperative systemic inflammatory response syndrome is often accompanied by endothelial dysfunction characterized by increased endothelial leukocyte adhesion and permeability (1). The resulting oedema and hyperinflammation significantly contributes to organ failure in critically ill patients and substantially worsens patient outcomes. Previous studies have demonstrated an anti-inflammatory effect of the ketone body beta-hydroxybutyrate (BHB) on T-cell immunity (2).
**Objectives:** Therefore, we investigated the protective influence of BHB pre-incubation on endothelial cell function during acute inflammation and in a translational in-vitro model of postoperative endothelial dysfunction.
**Methods:** Primary endothelial cells (HUVEC) were subjected to shear stress at 10 dyn/cm$^2$ and incubated with or without BHB (NC vs. BHB) for 24 h. Subsequently, the cells were further activated for 24 h with 10 ng/ml TNF or with inflammatory serum obtained from patients after cardiopulmonary bypass. Metabolic activity was assessed using Seahorse Flux Analysis, and the inflammatory response was characterized using flow cytometry and ELISA. Following perfusion of calcein-labeled monocytes over the inflamed endothelium, monocyte adhesion was quantified using fluorescence microscopy. Endothelial barrier function was evaluated using electric cell-substrate impedance sensing (ECIS).
**Results:** We demonstrate that pre-incubation with BHB induced a fundamental reprogramming of the metabolic profile in inflamed endothelial cells: the TNF-induced increase in glycolysis was significantly reduced (Fig. 1A, GlycoPER − 19.6%, $p<0.05$). Additionally, BHB stabilized mitochondrial membrane potential (Fig. 1B, JC1 + 13.7%, $p<0.05$) and reduced mitochondrial reactive oxygen species (Fig. 1C, mROS − 22.7%, $p<0.01$). The elevated secretion of cytokines (IL-6

− 21.4%, $p < 0.05$), chemokines (Fig. 1D, CCL2 − 35.0%, $p < 0.05$), and the surface expression of endothelial cell adhesion molecules were markedly decreased by BHB pre-incubation (Fig. 1E, ICAM-1 − 12.9%, $p < 0.05$). Consistent with these findings, endothelial monocyte adhesion following TNF stimulation was significantly reduced in BHB-pretreated endothelium (Fig. 1F, Monocytes − 18.2%, $p < 0.05$), while barrier function was strengthened (Fig. 1G, ECIS + 5.6%, $p < 0.05$). Pre-incubation with BHB also resulted in markedly decreased endothelial inflammation following stimulation with postoperative serum from cardiac surgery patients (Monocytes − 33.1%, $p < 0.05$; ECIS + 9.1%, $p < 0.05$). At the molecular level, BHB pre-incubation led to reduced activation of pro-inflammatory NFκB and ERK pathways (Fig. 1H, I, *p*-IκB − 26.4%, $p < 0.05$; *p*-ERK − 20.8%, $p < 0.01$).

**Conclusions:** BHB-mediated reprogramming of the metabolic profile in human endothelial cells results in a reduction of endothelial dysfunction during the acute inflammatory response. These findings highlight the anti-inflammatory potential of BHB supplementation as a possible preventive measure to reduce postoperative complications in the ICU by preserving endothelial function.

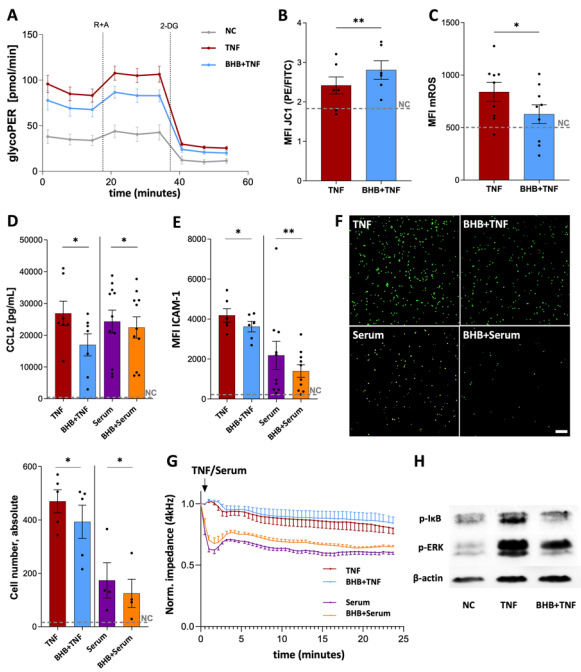

**Fig. 1 (abstract 001560)** Metabolic and inflammatory activation of HUVEC under basal, stimulated, and BHB-supplemented conditions
HUVEC were cultured under shear stress with or without BHB for 48 h and stimulated with TNF or inflammatory serum from postoperative cardiac surgery patients for an additional 24 h. ## Evaluating the quality of systematic reviews on the use of balanced crystalloids versus saline in fluid resuscitation of critically ill patients

L.V.D.W.B.U. Andari[1], N.D. Acherman[1], A. Alves da Silva[1]
[1]Critical Care Unit, Albert Einstein Israelite Hospital, São Paulo, Brazil
**Correspondence:** A. Alves da Silva
***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001561

**Introduction:** Intravenous fluid therapy remains a cornerstone in the management of critically ill patients, with the debate between the use of balanced crystalloid solutions and saline continuing to garner significant clinical attention. The choice of resuscitative fluid can profoundly impact patient outcomes, particularly in critically ill populations where fluid balance and composition are pivotal. Recent systematic reviews have endeavoured to synthesize available evidence, comparing the efficacy and safety of balanced crystalloids to saline, yet the quality of these reviews varies, potentially influencing the strength of their conclusions and recommendations. This study aims to dissect and appraise the methodological rigour and quality of these systematic reviews to provide clarity on the implications of their findings for clinical practice. By assessing the quality of systematic reviews, we can better understand the landscape of evidence guiding fluid therapy in critically ill patients and ensure that healthcare decisions are informed by robust, high-quality research.
**Objectives:** This study employed a comprehensive meta-research approach, systematically evaluating the methodological quality of published systematic reviews that compared balanced crystalloids with saline for fluid resuscitation in critically ill patients.
**Methods:** We meticulously searched databases including MEDLINE, EMBASE, Web of Science, and the Cochrane CENTRAL Register of Controlled Trials up to December 2019, ensuring a broad capture of relevant literature.
Stringent inclusion criteria, requiring studies to be systematic reviews with or without meta-analysis, focusing on adult critically ill patients, and comparing balanced crystalloids to saline. The primary outcomes of interest were mortality and renal replacement therapy (RRT), while secondary outcomes included ICU length of stay and incidence of acute kidney injury (AKI).
Each systematic review's quality was assessed using the AMSTAR (A Measurement Tool to Assess Systematic Reviews) tool, and the certainty of the evidence was evaluated using the GRADE (Grading of Recommendations Assessment, Development, and Evaluation) approach.
**Results:** Our analysis included a total of six studies, with sample sizes ranging from 19,105 to 35,456 participants, and encompassing various critical care scenarios.
We synthesized and presented the extracted data in a tabular format, summarizing key aspects such as the number of randomized controlled trials (RCTs) included, the quality of evidence, and the consistency of the findings across the reviews. The table also denotes whether each study reported on specific outcomes of interest, providing a clear and concise comparison of the evidence base.
This methods section is tailored to fit the context of the abstract and aligns with the information provided in the table.

**Conclusions:** The necessity for rigorous methodological standards in conducting systematic reviews and meta-analyses is underscored by our findings. It is evident that the variability in review quality can significantly impact clinical decision-making. To enhance the reliability of conclusions drawn from systematic reviews, adherence to established protocols such as PRISMA guidelines, thorough risk of bias assessments, and the use of the GRADE approach for grading the quality of evidence should be considered mandatory.
It is imperative that future reviews incorporate these stringent methodological practices to ensure that healthcare professionals can base their decisions on the highest quality evidence. This will foster better clinical outcomes and strengthen the confidence of the medical community in the synthesized findings of systematic reviews and meta-analyses in the field of critical care medicine.

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001562

**Introduction:** A complementary approach to the management of bacterial infections is the use of host-directed therapies that can interfere with host cell factors required by a pathogen for replication or persistence [1].
Therapies targeting the humoral immune response in bacterial sepsis remain relatively unexplored, however, early work demonstrates that trimodulin (human polyvalent immunoglobulin) and plasma exchange may be of benefit in patients with septic shock [2–3].
The need for host-directed therapies in sepsis is of particular relevance given many patients succumb to persistent and/or secondary infections that are generally associated with impaired immune function (sepsis-induced immunosuppression).
**Objectives:** Identify whether serum isolated from septic patients has impaired antimicrobial and immunomodulatory properties compared to serum isolated from volunteers.
**Methods:** The antimicrobial effect of serum was assessed by incubating serum from healthy volunteers (HV) and ICU patients (both survivors and non-survivors) with or without heat treatment (to denature proteins), for 24 h with gram-negative bacteria (Acinetobacter, E. coli, Klebsiella and Pseudomonas) in the presence or absence of antibiotics (meropenem, ciprofloxacin, and gentamicin). The effect on bacterial growth was assessed using optical densities and a number of colony-forming units and the co-effect with meropenem was assessed using minimum inhibitory concentration.
The immunomodulatory effect of serum was assessed by incubation of HV peripheral blood mononuclear cells (PBMCs) for 24 h (monocytes, with and without heat-killed E coli [HKB]) or 72 h (lymphocytes, with or without CD3/ CD28 beads) with pooled serum from volunteers, ITU survivors and non-survivors. The effect on the immune function of monocytes (chemokine receptor expression, phagocytosis, antigen presentation, cytokine release, and T-cell suppression) and lymphocytes (activation, proliferation, cytokine release, and cell death) was assessed by flow cytometry.
**Results:** The growth of Gram-negative bacteria is inhibited by HV ($n=5$) serum in vitro. Heat treatment of the serum to denature proteins resulted in the loss of antimicrobial properties. (Fig a.i. example with actinobacteria) This ability to inhibit bacterial growth was impaired in serum taken from critically ill septic patients ($n=3$), but not in serum taken from patients with milder infections. (data not shown) Additionally, healthy volunteer serum had a synergistic effect with antibiotics in preventing the growth of bacteria in vitro. (Fig a.ii. example with meropenem).
In PBMCs co-incubated with HKB or beads and pooled serum from volunteers ($n=6$), ICU survivors ($n=6$) or non-survivors ($n=3$), monocyte phagocytosis was decreased; the effect was more pronounced in the presence of serum from patients with sepsis (Fig b.i.). Serum from patients with sepsis resulted in a reduction in monocyte HLA-DR expression compared to serum from HV. This was more pronounced in serum from sepsis non-survivors. (data not shown) Serum from patients with sepsis resulted in an increase in CTLA-4 compared to HV serum (Fig b.ii.) and a reduction in CD4 + lymphocyte CD28 (data not shown) indicative of an immunosuppressive phenotype. Similar effects were seen in CD8 + lymphocytes (data not shown).
**Conclusions:** Healthy volunteer serum has antimicrobial properties and has a synergistic effect with antibiotics in preventing the growth of bacteria in vitro. This effect is progressively lost with increasing severity of illness.
Serum from patients with sepsis induces an immunosuppressive phenotype when incubated with volunteer immune cells.
This effect may be related to depletion, inhibition or augmentation of putative factors. Identification of these factors would enable the development of a therapeutic intervention to replenish responsible serum component (s) and improve outcomes from sepsis.

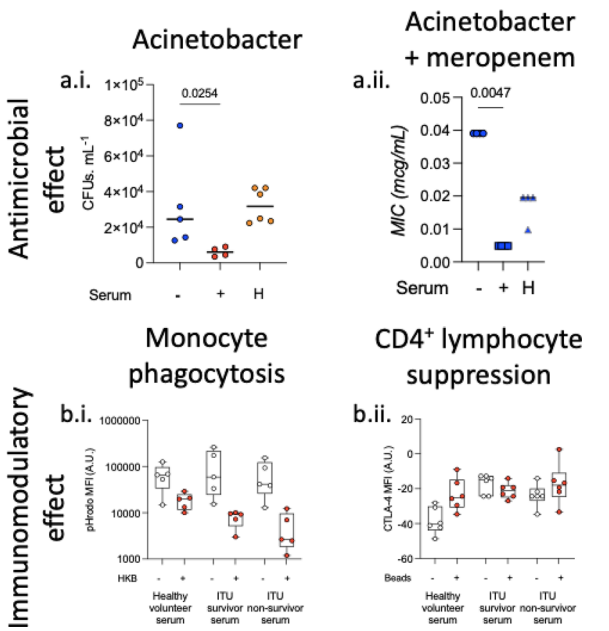

**Fig. 1 (abstract 001562)** Healthy volunteer serum has antimicrobial properties against gram-negative bacteria (a.i.) and enhances the antimicrobial effect of antibiotics (a.ii.) This effect is lost after heat treatment. Septic patient serum has immunosuppressive effects, reducing monocyte phagocytosis (b.i.) and increasing CD4 + lymphocyte suppression (b.ii.)

### Severe trauma patients: does time before ICU admission matter?

H. Macedo[1], S.C. Alves[1], H. Veiga[1], S. Teixeira[1], D. Araújo[1], J. Amado[1], N. Gatta[1], J.M. Pereira[1], J.A. Paiva[1]

**Correspondence:** H. Macedo
*Intensive Care Medicine Experimental* 2024, **12 (suppl 1)**: 001564

**Introduction:** Time is vital in trauma since delay in its management carries high morbimortality. After initial stabilization in the Emergency Department (ED), severe trauma patients are frequently admitted to the ICU. Since the outcome of these patients is often dependent on time-sensitive care intervention, the timing of transfer to the ICU may be extremely important.

**Objectives:** To evaluate the impact of time spent in the ED before ICU admission on the outcome of critically ill trauma patients.
**Methods:** Retrospective single-center study of all trauma patients admitted between June and December of 2023 to an ICU of a Tertiary University Hospital. Time spent in the ED before ICU admission was divided into 3 groups: ≤ 3 h (group I), 3 to 6 h (group II) and ≥ 6 h (group III). Besides demographic data, we collected severity scores, serum lactate, arterial pH level and systolic blood pressure on ED admission, Shock Index (SI), the need for emergency surgery, length of stay (LOS) and ICU and hospital mortality. SPSS was used for statistical analysis.
**Results:** During this period, 89 trauma patients were admitted, mainly male (76.4%), median age of 56y (IQR 38.5–65) and 33.7% had ≥ 1 comorbidity. Most of the patients were polytrauma with brain injury (BI) (46.1%), 14.6% had isolated BI and 19.1% had monotrauma. Median time in ED was 4.74 h and 53.9% were submitted to emergent surgery. Median ICU and hospital LOS were 5 (IQR 2–10) and 13 (5–29.5) days, respectively. ICU mortality was 11.2% which increased to 12.4% regarding hospital mortality.
Groups I, II and III included 26 (29.2%), 36 (40.5%) and 27 (30.3%) patients, respectively. No difference between groups was observed regarding gender, age, presence of comorbidities and SAPS II. Although not statistically significant ($p = 0.067$), patients in group I had, more frequent, monotrauma (38.5%) while patients in group II and III had more frequent polytrauma with BI in 50% and 59.3% patients, respectively. However, patients in group I were more frequently submitted to emergent surgery (80.8 vs 41.7 vs 44.4%; $p = 0.005$).
No significant differences were observed regarding median serum lactate, arterial pH and SI on admission to ED (Table 1).
Both ICU (19.2 vs 8.3 and 7.4%, respectively; $p = 0.306$) and hospital (19.2 vs 11.3 and 7.4%, respectively; $p = 0.407$) mortality were higher in group I but not reaching significant differences.
No differences between the 3 groups were found regarding ICU LOS (4.5 vs 5 vs 5 days; $p = 0.733$) but patients in group II (21.5 days) had a significantly longer hospital LOS compared to group I (8 days) and III (8 days) ($p = 0.043$).

**Table 1 (abstract 001564)** Median SI, pH level and lactate level (mmol/L) within each group in the ED

| | Group I | Group II | Group III | *p* = |
|---|---|---|---|---|
| SI | 0.75 | 0.84 | 0.69 | 0.139 |
| Arterial pH | 7.34 | 7.36 | 7.37 | 0.603 |
| Lactate (mmol/l) | 1.58 | 2.21 | 1.87 | 0.106 |

**Conclusions:** Time spent in the ED before ICU admission did not significantly impact the outcome of trauma patients, except on hospital LOS. The constant presence of an intensivist in the ED, leading the initial approach to these patients may be one of the determinants of the lack of impact of time in the ED pre-ICU on most outcome variables.
For most of the severe trauma patients, the Intensive Care Unit is the first hospital service they are admitted to after emergency admission. Furthermore, trauma carries high morbidity and mortality, and the treatment must be carried out without delay. Efforts have been made to study the impact of time spent in ED on patient's outcome.

### Preoperative carbohydrate loading to maintain normothermia in children under anaesthesia: A prospective randomised controlled trial

A. Singh[1], S. Puri[1], V. Ganesh[1], N. Bharadwaj[1]
[1]Anaesthesia and Intensive Care, Post Graduate Institute of Medical Education & Research, Chandigarh, Chandigarh, India
**Correspondence:** A. Singh
*Intensive Care Medicine Experimental* 2024, **12 (suppl 1)**: 001565

**Introduction:** Infants and children are prone to develop hypothermia under anaesthesia. The consequences of hypothermia contribute to adverse outcomes such as bleeding as well as altering the pharmacokinetics and pharmacodynamics of various drugs administered. Maintenance of normothermia is therefore of paramount importance.
**Objectives:** The present study is designed to evaluate the efficacy of preoperative oral carbohydrate administration in reducing intraoperative hypothermia.
**Methods:** After taking institutional ethical approval and consent from parents/legal guardian children of ASA PS 1 and 2 between the age group 2–10 years, posted for urogenital surgeries under general anaesthesia (GA) lasting for more than 30 min were screened for randomized allocation. Group Oral Carbohydrate (group A) patients received 5 ml/kg of oral carbohydrate solution (glucon-D) prepared as 12.6% solution. The solution was prepared by adding 0.7 gm/kg of glucon-D to water. Group B children were administered 5 ml/kg of plain water. Both solutions were administered 2 h prior to surgery as per the group. Before induction of anaesthesia baseline tympanic infrared temperature (TB) was recorded. The operation theatre temperature was monitored and maintained at 25–27 degree Celsius. Any intraoperative temperature recording < 36 degree Celsius (tympanic infrared, recorded every 15 min) was labelled as hypothermia. The temperature at the end of surgery and before extubation was recorded, i.e. final temperature (TF). The difference between TB and TF was calculated and compared in the two groups.
**Results:** Hundred and sixteen patients were recruited between November 2021 and December 2023. There was no imbalance in the baseline parameters. Preoperative oral carbohydrate administration (group A) changed the incidence of intraoperative hypothermia by − 21% [95% CI, − 39 to − 2.1%, $p = 0.032$]. The incidence of postoperative shivering was also lower in the oral carbohydrate group − 17% [− 30 to − 4.9%, $p = 0.006$]. There was no difference in the total intraoperative fluid administered or blood loss. There was no difference in the intraoperative blood glucose levels.
**Conclusions:** Preoperative oral carbohydrate administration can reduce the incidence of intraoperative hypothermia and postoperative shivering in children aged 2–10 years presenting for urogenital surgeries.

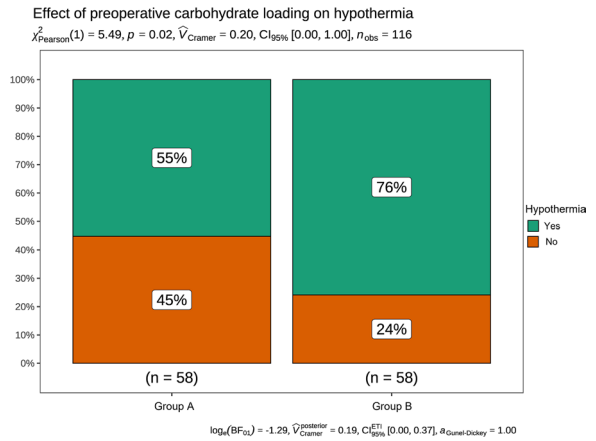

**Fig. (abstract 001565)** Incidence of hypothermia in each group; Group A—preoperative oral carbohydrate group, Group B—Placebo group

### Complete blood count ratios interest in diagnosis of pulmonary embolism

E. Rachdi[1], Y. Kharrat[2], S. Ben Brahim[1], F. Jarraya[1], N. Ben Mrad[3], A. Jamoussi[1], S. Ayed[4], J. Ben Khelil[1]
[1]Intensive Care, Hôpital Abderrahmen Mami de Pneumo-Phtisiologie, Ariana, Tunisia, [2]Intensive Care Unit, Abderrahmen Mami Pneumo-Phthisiology Hospital, Ariana, Tunisia, [3]Intensive care, Hopital Abderrahman Mami, Tunis, Tunisia, [4]Intensive Care, Abderrahmen Mami Hospital, Ariana, Tunisia
**Correspondence:** E. Rachdi
***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001566

**Introduction:** White blood cells (WBC) subtypes have been associated with many several inflammatory diseases such as pulmonary embolism (PE). The neutrophil–lymphocyte ratio (NLR), monocyte-lymphocyte ratio (MLR), and platelet-lymphocyte ratio (PLR) are easily assessable and continue to hold significance today. These parameters have been identified as potentially beneficial biomarkers for assessing the prognosis of patients with PE.
**Objectives:** To study the interest of WBC subtypes ratios in predicting the diagnosis of PE in patients admitted for acute respiratory failure.
**Methods:** It was a retrospective study including patients admitted for the management of acute respiratory failure in the absence of radiographic findings. The study took place in the medical intensive care unit at Abderrahmen Mami Hospital in Ariana, Tunisia between January 2023 and December 2023. Demographic, clinical and outcome data were collected. The NLR, MLR, PLR, eosinophil-lymphocyte ratio (ELR) and basophil-lymphocyte ratio (BLR) were calculated at Day 1 of care. Two groups were individualized using CT scan angiography: G1 = EP + and G2 = EP−. The correlation between the ratio and PE was investigated using the student test T.
**Results:** Eighty-three patients were included. The mean age was 55.5 ± 19.3 years with a gender ratio of 0.9. Median APACH II score was 8 [5–14] and mean IGS2 score was 28 ± 18. Forty-seven patients were admitted for the management of hypercapnic acute respiratory failure, and 37 for non-hypercapnic acute respiratory failure. The diagnosis of PE was made in 28 patients (34%). The NLR, MLR, PLR, and BLR were not associated with the occurrence of PE (respectively $p = 0.2$; 0.4; 0.3; 0.2). However, the ELR was significantly lower in patients of EP + comparatively with those of EP− (respectively, 0.08 vs 0.15; $p = 0.01$).
**Conclusions:** Our study findings demonstrated that the analysis of the ELR ratio on day one of hospitalisation may predict the occurrence of PE. Larger studies are required to confirm our results.

**Topic:** Acute respiratory failure and mechanical ventilation

### Retrospective evaluation of cerebral Near-Infrared Spectroscopy (NIRS) monitoring in patients undergoing venoarterial extracorporeal membrane oxygenation (V-A ECMO) treatment

S.S. Ferreira Custódio[1], P. Rodrigues Sanches[1], E.J.P.V. Oliveira[1], P.P.Z.D.A. Campos[1], A. Alves da Silva[1]
[1]Critical Care Unit, Albert Einstein Israelite Hospital, São Paulo, Brazil
**Correspondence:** A. Alves da Silva
***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001567

**Introduction:** Extracorporeal membrane oxygenation (ECMO) provides advanced bridge therapy for refractory cardiopulmonary failure and perioperative support, including refractory cardiopulmonary resuscitation (1), improving survival and neurological outcomes (2). Despite advancements, ECMO remains associated with high morbidity, especially neurological complications like seizures, intracranial hemorrhage, and ischemic stroke, more prevalent in V-A ECMO than V-V

ECMO (4), and in extracorporeal cardiopulmonary resuscitation (ECPR) (5). Adequate neurological monitoring, including clinical examination and tools like bispectral index (BIS) and near-infrared light spectroscopy (NIRS) (6,7), is crucial. This study aims to assess functional, clinical, and neurological changes during V-A ECMO and their correlation with cerebral NIRS regional oxygen saturation (rSO2).

**Objectives:** To evaluate the correlation between rSO2 levels verified by cerebral NIRS of patients on V-A ECMO and the Modified Rankin functional assessment scale (mRS) within a period of up to 28 days after the start of monitoring. Secondary objectives include the correlation of rSO2 levels with length of stay in the ICU, mechanical ventilation time, neurological complications and other clinical features.

**Methods:** This was a single-center, retrospective cohort study of patients who received support with V-A ECMO and neurological monitoring with cerebral NIRS treated at the Critical Care Department of Hospital Israelita Albert Einstein (HIAE) in São Paulo, SP, during the period from January 2015 until July 2023. Data was extracted from the electronic medical record, EPIMED database of HIAE and ECMO-related database of the Critical Care Department of HIAE. This study was approved by the Research Ethics Committee of Hospital Israelita Albert Einstein (CAAE: 73,955,623.7.0000.0071; # 6.433.403). Informed consent was waived due to retrospective design. Adults between 18 and 70 years old treated with V-A ECMO and monitored with cerebral NIRS were included.

**Results:** Twenty-three out of 55 V-A ECMO patients (aged 47 [18–70] years) were included. The mean SAPS-3 score on admission was 46.35 ± 12.77. 15 individuals (65.2%) were male, and 8 individuals (34.8%) were female. 15 patients (65.2%) survived, and 8 patients (34.8%) died. 1 patient (4.3%) had chronic kidney disease requiring dialysis. 6 patients (26.1%) were hypertensive. 7 patients (30.4%) had diabetes. 1 patient (4.3%) was a smoker. 1 patient (4.3%) was an alcoholic. 18 patients (78.3%) were diagnosed with septic shock. 9 patients (39.1%) were cannulated due to cardiogenic shock, 6 (26.1%) due to ECPR, and 8 (34.8%) due to heart or lung transplantation. The mean duration of V-A ECMO treatment was 7.04 days ± 7.125, with a minimum of 1 day and a maximum of 26 days. The most frequent treatment duration was 4 days (21.7%). The mean mRS after 28 days of ECMO initiation was 3.26 ± 2.43, with 0 being the most frequent result (30.4%), 8 patients with a score of 0–2, and 15 patients with a score of 3–6. The mean ECMO flow was 3.15 ± 0.76. The mean membrane oxygen fraction (FmO2) was 57.29% ± 18.35. The mean mean arterial pressure (MAP) was 71.59 ± 11.28. The mean left cerebral rSO2 was 52.53 ± 10.41, and the right cerebral rSO2 was 52.925 ± 10.45. Multivariate regression analysis showed that mean arterial pressure (MAP) was significantly associated with NIRS levels in both the right ($p < 0.033$) and left ($p < 0.008$) cerebral hemispheres.

**Conclusions:** In conclusion, our retrospective analysis emphasizes the critical need for neurological monitoring in venoarterial extracorporeal membrane oxygenation (V-A ECMO) patients due to the persistent risk of neurological complications. Particularly, the observed correlation between mean arterial pressure (MAP) and NIRS levels underscores the importance of effective hemodynamic management in maintaining cerebral perfusion during V-A ECMO therapy.

### PCT/PCR index as a predictor of mortality in pulmonary sepsis

M. Araujo Palacios[1], G. Aguirre-Gomez[1], O.I. Aguilera Olvera[1], J.A. Villalobos Silva[1], M.I. Muñoz Treviño[1], I.S. Salazar Puente[1], M.R.F. Martinez[1]

**Introduction:** C-reactive protein (CRP) and procalcitonin (PCT), the cheapest and most readily available, are by far the most routinely used biomarkers for sepsis (1). A study conducted on patients with abdominal sepsis, the PC/CRP index showed better performance than PCR and PCT alone (2). We postulate that the utilization of the PCT/CRP index in pulmonary sepsis would show the same results as abdominal sepsis.

**Objectives:** Examine the predictive efficacy of the PCT/PCR index for mortality in patients with pulmonary sepsis.

**Methods:** Prospective cohort of adult patients admitted to an ICU in Mexico, continuous and categorical variables were described as mean/standard deviation and percentages, respectively, and compared with student *t* test or chi-squared as appropriate.

**Results:** 19 patients were included, all with pulmonary sepsis, male/female $n = 9/10$, mean age 55 years (± 17), BMI 29.4 kg/m2 (± 8.6), 21% had a stroke ($n = 4$), coronary heart disease 10% ($n = 2$), heart failure 10% ($n = 2$), hypertension 53% ($n = 10$), COPD 16% ($n = 3$), chronic kidney disease 26% ($n = 5$), T2DM 37% ($n = 7$), vasopressor 89% $n =$ (17), mechanical ventilation 95% ($n = 18$), oliguria defined as uresis < 30 ml/hr 79% ($n = 15$), admission origin ER 36% ($n = 5$), Ward 68% ($n = 13$), OR 5% ($n = 1$). Clinical measurements as HR was 107 bpm (± 26), RR 27 rpm (± 7), MAP 89 mmHg (± 20), SBP 125 mmHg (± 29), DBP 70 mmHg (± 16), SO2 95% (± 4). Laboratory variables total leukocyte count was 16150cel/mm3 (± 7581), neutrophil count 14357cel/mm3 (± 7400), lymphocyte count 926cel/mm3 (± 479), NL ratio 19.9 (± 16.7), haemoglobin 11.3gr/dl (± 3), hematocrit 34.4% (± 9.4), paO2 92 mmHg (± 49.3), paCO2 46.4 mmHg (± 12.7), lactate 2.3 mmol/l (± 2), HCO3- 39.4 mEq/l (± 58.2), creatinine 1.6 mg/dl (± 1.3), albumin 2.9gr/dl (± 0.6), C-reactive protein 0.21 mg/ml (± 0.11), CRP/albumin ratio 77.2 (± 47.4), procalcitonin 8.1 (± 17.3), PCT/CRP ratio 42 (± 92), prognostic scores SOFA 8 (± 3) SAPS 50 (± 24), mechanical ventilation days 10 (± 8). Renal replacement therapy 26% ($n = 5$), and mortality

was 42% ($n=8$). AUC ROC was elaborated (Fig. 1) CRP/albumin ratio 0.53, PCT/CRP ratio 0.69, SOFA 0.76 SAPS 0.5. PCT/CRP ratio cutt-off value 9.4 had a sensitivity of 75%, specificity 64%, PPV 60% NPV 78%. Statistical difference was found in creatinine between both groups (< 9.4/ > 9.4) $p=0.006$, RRT 0% vs 26% with odds ratio 2.8 (CI 95% 1.38–5.6, $p=0.01$) (Fig. 2). No statistical difference was found between both groups in mortality 21% vs 36% with an odds ratio 5.2 (CI 95% 0.69–39.4, $p=0.09$).

**Conclusions:** Statistically, the PCT/CRP index demonstrates moderate predictive value, while SOFA and SAPS II stand out as predictors of mortality among patients with pulmonary sepsis. Notably, a cut-off value of 9.4 in the PCT/CRP index proves valuable in identifying pulmonary sepsis patients who are less likely to require acute kidney injury assessment or renal replacement therapy.

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001570

**Introduction:** Interhospital transports and mortality in critically ill COVID-19 patients: a single center cohort study.

**Objectives:** Interhospital transport (IHT) is relatively common in intensive care, the main reasons for IHTs are either the need for specialized care, diagnostics, or treatment or due to resource constraints in the current hospital. While IHT can offer benefits to patients, it also comes with inherent risks associated with the transport process itself, as well as potential delays in diagnosis, treatment, and prolonged ICU stays. During the COVID-19 pandemic, the influx of critically ill patients led to a notable increase in IHT cases. Studies exploring the risk of IHT during this period have presented conflicting results. Some research suggests that IHT is linked to prolonged mechanical ventilation, more extensive

treatments, and longer hospital stays, while others have found no association with hospital duration or mortality rates.
**Methods:** The aim was to compare mortality rate and hospital length of stay among patients with critical COVID-19 in Sweden who were transferred to another hospital and those who remained in the hospital where they were initially admitted to.
**Results:** In total, 651 SARS-CoV-2 ICU-treated patients were included in the study, of which 133 (20%) underwent IHT. Compared with non-IHT patients, a smaller proportion of IHT patients were deceased within 30 days of ICU admission (19% versus 25%) and for 90 days (26% versus 29%). IHT was associated with a decreased risk of mortality at 30 days (HR 0.50, 95%CI: 0.31–0.80) as well as for 90 days (HR 0.54, 95%CI: 0.36–0.81). The transferred patients spent longer time in the hospital and had fewer days alive free of ICU during 30 days of ICU admission and 90 days. For 30-day survival, patients with IHT had fewer days alive and free of ICU (median: 5, IQR: 0–18) than non-transferred patients (median: 22, IQR: 0–27, $p < 0.001$).
**Conclusions:** In this study, transfer because of a lack of intensive care capacity during the COVID-19 pandemic was associated with a reduced risk of short-term mortality among critically ill ICU patients with severe SARS-CoV-2 infection. However, transferred patients had longer ICU stays compared to patients who remained in the admitting ICU. Sensitivity analyses confirmed the results.

### Risk factors for multiresistant bacteria in critically ill children: the creation of the MDR-score

M. Girona[1], C. Gonzalez-Anleo[2], A. Casaldiga[2], S. Bobillo[1], A. Solé[1], E. Fresan Ruiz[1], M. Balaguer[1], I. Jordan Garcia[1]

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001571

**Introduction:** Healthcare-associated infections (HAI) are among the most important global health concerns, as they increase morbidity and mortality. Multidrug-resistant (MDR) bacteria imply a higher mortality, related to the delay in an adequate treatment.
Many researchers have studied risk factors related to MDR HAIs, but the majority of the knowledge is based on adults.
**Objectives:** The main aim was to identify specific risk factors for MDR infections in critically ill children and to create a risk score to predict MDR infections.
Secondary objectives were to analyse the outcomes of patients depending on the microorganisms' sensitivity.
**Methods:** This was a single-centre, prospective and observational study. Patients < 18 years, admitted to the Paediatric Intensive Care Unit (PICU) between 2015 and 2022, with device-associated HAI (DA-HAI) diagnosis (ventilator-associated pneumonia (VAP), catheter-associated urinary tract infections (CAUTI) and central line-associated bloodstream infections (CLABSI)) were included.
Variables that were significantly associated with MDR infections in the univariate analysis, were entered into multiple forward stepwise logistic regression models. The regression coefficients of each independent risk factor were used to build the risk score for MDR: MDR-score.
**Results:** 257 patients were included:106 VAP (41.2%), 91 CAUTI (35.4%), and 60 CLABSI (23.3%). The median age was 7 months (IQR 2–30).
Risk factors for MDR infection were: comorbidity ($p = 0.002$), previous colonization ($p = 0.002$), previous MDR colonization ($p < 0.001$), previous surgery ($p = 0.018$) and previous antibiotic treatment ($p = 0.009$). Days from device insertion and PICU admission to infection were longer in patients with MDR (14 vs. 12.5 days and 12 vs. 9 days, respectively, $p < 0.005$).
In the multivariate analysis, independent risk factors for MDR DA-HAI were comorbidity (OR 2.201), MDR previous colonization (OR 5.149), and length of stay (LOS) in PICU > 9 days (OR 1.782). With them, the MDR-score was created, and patients were divided into risk groups: low (0–2 points), intermediate (3–7 points), and high (8–12 points).
Then, 79 (30.7%) patients were classified as low risk, 131 (51.0%) as intermediate risk, and 47 (18.3%) as high risk for MDR.
From patients with MDR infections, 71 (82.6%) were classified in the intermediate or high-risk group. Also, the high-risk group showed a great specificity (91.8%). But 81.0% of patients stratified in the low-risk group had non-MDR infections, thus they were correctly classified.
Patients with MDR infections were treated with an incorrect empiric antibiotic (40.7% vs. 6.8%, $p < 0.001$), had a longer LOS in PICU (25.5 vs. 21.0%, $p = 0.021$) and a higher mortality (11.6. vs 6.4%, $p = 0.151$).
**Conclusions:** The MDR-score includes three main risk factors related to MDR DA-HAI: comorbidity, previous MDR colonisation, and LOS in PICU > 9 days. This score might be useful to guide the empirical therapy election, providing an early optimization and avoiding delays in the establishment of an appropriate treatment.

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001572

**Introduction:** Patients who experience an admission to Intensive Care Medicine (ICM) are likely to need sedation and may present no memories about that period after discharge. Those who remember present a huge variety of memories. Therefore, it is important to analyze further information about them.
**Objectives:** To characterize memories from ICM hospitalization and understanding which factors can have more influence in developing delusional memories.
**Methods:** Patients admitted to an ICM department between June and November 2023 were included in this retrospective study. We selected those observed in our follow-up clinic who have reported any type of memory. They were asked to fill an Intensive Care Unity Memory Tool (ICUMT) with a checklist of possible items to remember. Considering this group, it has been evaluated the presence of delirium, sepsis, and the need for invasive mechanical ventilation (IMV).
**Results:** From a total of 130 patients, 57 (44%) were included. Median age was 65 years old, 81% male. Sepsis was present in 75%. On average, the total duration of ICM stay was 9 days (5 days in level 3 of critical care) and IMV was performed in 32%, median of 3 days. Delirium was observed in 39%. Follow-up occurred, in average, 120 days after discharge. Admission to hospital was clearly remembered in 72%, and total staying in ICM in 67%. Factual memories were described in 82%: 65% remembered their family visit, 37% lights and alarms, 30% voices, 35% having a breathing tube and 16% darkness. Emotional memories such as confusion (30%), feeling down (33%), anxiety and fear (21%) and discomfort (32%) were observed in 51%. Delusional memories were reported in 33%, including dreams or nightmares (30%), hallucinations (7%) and feeling that someone was trying to hurt them (5%). Patients submitted to IMV presented 2,7 times higher probability of claiming delusional memories—odds ratio (OR) 2,7; those with sepsis had a probability 2,4 times higher (*OR* 2,4) and in the case of delirium the OR was 1,5. Pittsburgh Sleep Quality Index above 5 was more prevalent in the group of patients with delusional memories compared to patients who did not have these memories (75% vs 49%). Higher median EuroQol five-dimension five-level questionnaire score was observed in the group of patients with delusional memories (10 vs 8). Psychological post-intensive care syndrome was identified in 14% of patients and 50% of these described delusional memories.
**Conclusions:** Although this study includes a small sample, it showed that there is a great percentage of critical care survivors who do not remember their ICM stay. Factual memories were the most recalled, followed by emotional ones. Presence of sepsis or delirium showed a higher probability of developing delusional memories as well as the need for IMV. Patients with this type of memories also might present less quality of sleep and health-related quality of life. Nevertheless, there is still few evidence about ICM memories which deserves further exploration.

## Evaluating heterogeneity in the response to surviving sepsis campaign guidelines

J. Digitale[1], A. Kalimouttou[2], A. Waschka[3], N. Fong[4], A. Hubbard[3], R. Pirracchio[5]
[1]Department of Anaesthesia and Peri-Operative Care, Zuckerberg San Francisco General Hospital And Trauma Centre, San Francisco, United States of America, [2]Intensive Care Unit, Cochin Hospital, Paris, France, [3]Biostatistics, UC Berkeley, Berkeley, United States of America, [4]Anesthesia and Perioperative Medicine, UCSF Medical Center at Mission Bay, San Francisco, United States of America, [5]Department of Anaesthesia and Peri-operative Care,, Zuckerberg San Francisco General Hospital And Trauma Centre, san francisco, France
**Correspondence:** R. Pirracchio
***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001573

**Introduction:** The Surviving Sepsis Campaign [1] (SSC) published recommendations for the management of sepsis that provide guidance to clinicians on a wide range of topics including resuscitation, treatment of infection, hemodynamic management, ventilation, and other relevant therapies. While some recommendations are based on high-quality evidence, many others are based on low or very low-quality evidence. Thus, for some of the recommendations, the true treatment effect remains unknown or poorly estimated.
Furthermore, sepsis is increasingly being recognized as a heterogenous disease, with large amounts of variability in the individual response to treatment. Little progress has been made thus far to advance precision medicine for sepsis. [2] While the SSC recognizes that for weak recommendations, "different choices are likely to be appropriate for different patients and therapy should be tailored to the individual patient's circumstances," there is no guidance on how to tailor therapy or which patients may benefit most from a given recommendation.
**Objectives:** Our aim is to estimate the average treatment effects (ATE) and the individual treatment effects (ITE) for SSC recommendations to assess for heterogeneity in treatment response.
**Methods:** We used the MIMIC-IV database [4,5] and included patients with sepsis and septic shock between 2008 and 2019. For each SSC Recommendation, the binary exposure was defined as following vs. not following the recommendation. The outcome was death at 28 days from hospital admission. Baseline covariates included demographics, medical history, vital signs, lab values, and mortality risk scores. All analyses were stratified by sepsis vs. septic shock.
We first identified which recommendations had sufficient variability in adherence to estimate treatment effects. We proceeded if there was $\geq$ 5% variation in adherence to the recommendation. We used targeted maximum likelihood estimation (TMLE) [7] to estimate the ATE. Heterogeneity of the treatment effect was quantified by estimating the standard deviation of the ITE using TMLE.
**Results:** We included 19,643 with sepsis and 2861 with septic shock. Out of 23 recommendations, 12 recommendations had $\geq$ 5% treatment variability in sepsis patients and 18 did in septic shock patients. ATEs vs. standard deviation of the ITE are illustrated in Figs. 1 and 2. Two recommendations for sepsis and four for septic shock had statistically significant heterogeneity in the ITE (Table 1). In sepsis patients, the recommendation with the most variability was the recommendation for ICU admission within 6 h of sepsis; in shock patients, it was the recommendation to start steroid supplementation if norepinephrine > 0.25ug/kg/min for more than 4 h.
**(abstract 001573)**

| | Average treatment effect | | | Variance of the individual treatment effect | | | |
|---|---|---|---|---|---|---|---|
| **Recommendation** | **Treatment effect** | **95% CI** | | **Root (Variance)** | **Variance** | **95% CI** | |
| *Sepsis* | | | | | | | |
| ICU admission | − 0.04 | − 0.04 | − 0.03 | 0.03 | 0.0007 | 0.0004 | 0.0010 |
| Lactate within first hour | 0.00 | 0.00 | 0.01 | 0.02 | 0.0003 | 0.0000 | 0.0005 |
| *Septic shock* | | | | | | | |

| Recommendation | Average treatment effect | | | Variance of the individual treatment effect | | | |
|---|---|---|---|---|---|---|---|
| | Treatment effect | 95% CI | | Root (Variance) | Variance | 95% CI | |
| ICU admission | 0.01 | − 0.01 | 0.04 | 0.04 | 0.0019 | 0.0006 | 0.0031 |
| Antibiotics within first hour | − 0.05 | − 0.07 | − 0.03 | 0.04 | 0.0019 | 0.0006 | 0.0031 |
| Steroids | − 0.19 | − 0.21 | − 0.17 | 0.07 | 0.0049 | 0.0013 | 0.0086 |
| MAP goal ≥ 65 mmHg | 0.00 | − 0.02 | 0.02 | 0.02 | 0.0006 | 0.0000 | 0.0012 |

**Conclusions:** The response to several SSC recommendations is highly variable. While following certain SSC guidelines may be very beneficial to some patients, but only somewhat beneficial or potentially even harmful to others. Identify subsets of recommendations and patients for which this is true, we could better prioritize care to maximize survival benefits for septic patients.

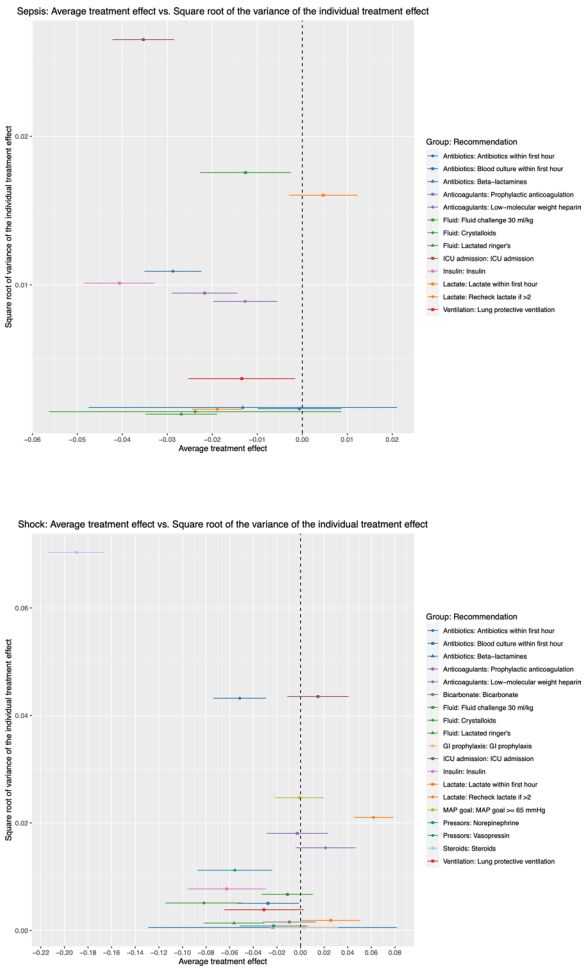

**Fig. 1 (abstract 001573)** Average treatment effect vs. Standard Deviation of the individual treatment effect (upper panel: Sepsis; lower panel: Septic Shock)
Horizontal lines are the 95% confidence intervals for the average treatment effect. The dashed vertical line represents no treatment effect.

### Use of POCUS to predict fluid responsiveness in hemodynamic management of shock: a systematic review

A.B.P. Marreiro[1], H.V. Luz[1], I. Fernandes De Melo Pereira[1], A. Gabriella Duarte De Queiroz[2], A.M. Lima[1], L.R.C.C. Silva[3], E.G. Lins[1], I. Melo[4], A.B.D. Lucena[5]

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001575

**Introduction:** Volume repositioning is crucial in the management of circulatory and septic shock, but half of patients do not respond to fluid therapy. Therefore, early detection of this profile is necessary to prevent cardiac overload. In this context, point-of-care ultrasound (POCUS) has emerged as a promising tool for assessing fluid status, tolerance, and responsiveness.
**Objectives:** To evaluate the use of POCUS to predict fluid responsiveness in the hemodynamic management of shock.
**Methods:** A systematic review was performed using the following combination of MESH terms and Boolean operators: "Fluid Responsiveness" AND "POCUS" AND "Fluid therapy" on the databases MEDLINE (PubMed), LILACS, and CENTRAL (Cochrane Library). Following PRISMA guidelines included studies from 2019 to 2024 in English or Portuguese.
**Results:** Six of the seven articles found in Pubmed, one of the three in Cochrane, and the article from Lilacs were selected, with a duplication in Pubmed and Cochrane. The exclusion criteria were narrative reviews, duplicate articles, animal tests, and theme fugue, resulting in seven articles to constitute this scope. Evidence has shown that parameters assessed by POCUS can predict the response to fluid therapy. Passive leg raising and static parameters, such as Inferior Vena Cava (IVC) diameter and systolic volume variation, assist in the decision to infuse fluids at the bedside. Although the Inferior Vena Cava Distensibility Index (ΔIVC) > 18% is a good indicator, it is only predictive in a specific subgroup of patients, similar to the variation in pulse pressure and systolic volume. Cavity dimension can also guide protective ventilatory measures and the interruption of fluid administration. Studies have shown that ΔIVC and ΔVpeak (respiratory variation in aortic blood flow peak velocity) are potential predictors of fluid response in children with septic shock under mechanical ventilation. In contrast, in spontaneously breathing children, only ΔVpeak was reliable. POCUS-guided fluid therapy in sepsis reduced the positive fluid balance at 72 h, preventing fluid overload and reducing the need for dialysis and invasive ventilation compared to empirical fluid therapy, but with no statistically significant change in 30-day mortality. In addition, POCUS identifies diastolic dysfunction and hypovolemia in patients with hypertrophic and thickened ventricles, preventing the use of inotropic drugs that could aggravate the obstruction and lead to cardiac arrest.
**Conclusions:** POCUS offers parameters for assessing responsiveness to fluid therapy, but defining cut-off points is challenging. Integration of clinical information, hemodynamic parameters, and POCUS guides resuscitation in shock. More research is needed to validate its use, especially in spontaneously breathing children.

**Introduction:** Volume expansion is a common initial treatment for circulatory failure. (1) Predicting fluid responsiveness (FR) is crucial, (2,3) as only about half of patients respond to volume expansion by enhancing cardiac output (CO). (4) Static parameters are unreliable predictors (5) and the use of dynamic tests is recommended to predict FR. (1,6) As such, the passive leg raising (PLR) test induces a reversable preload challenge and reliably predicts FR. (7) Assessing its effects, however, requires direct measurement of stroke volume (SV) or CO. SV and CO are typically obtained through methods with significant limitations such as invasiveness, availability and costs. (8) The perfusion index (PI) and pleth variability index (PVI) are non-invasive, readily available and inexpensive metrics derived from oxygen saturation signals and PI has been shown to be related to CO. (9,10).
**Objectives:** The primary objective was to evaluate the predictive capability of PI and PVI for predicting FR in post-surgical, spontaneously breathing patients undergoing a PLR test.
We hypothesized that in fluid responders the PI would increase and the PVI decrease.
**Methods:** This prospective interventional study was conducted in the intensive care unit of Merano Hospital, Italy, from April 2018 to March 2019.We enrolled adult spontaneously breathing patients following major abdominal surgery.
The FloTracTM system (uncalibrated pulse contour cardiac output monitor) was used for SV and CO determination. The Radical 7® monitor was employed for monitoring peripheral oxygen saturation (SpO2), PI, and PVI. Baseline values were recorded in a semi-recumbent position. Subsequently, a PLR test was conducted. Measurements of SV, CO, PI and PVI were recorded at 60-, 90-, and 120-s during PLR, as well as 3 min after the maneuver. Responders were defined as patients exhibiting an SV increase of ≥ 10% from baseline to 60 s into the PLR test measured with FloTracTM. Generalized linear mixed models were used and a receiver operating characteristics (ROC) curve was

generated to detect an increase of at least 10% in SV by the percentage changes in PI and the Youden index was used to determine the diagnostic threshold.

**Results:** A total of 71 PLR tests were performed. 46.7% of patients were fluid responders.

The percentage increase from baseline to 60 s into the PLR maneuver was 31.8% (95% CI 20.1–44.7%) for responders and 12.4% (95% CI 3.3–22.3%) for non- responders (Fig. 1).

An increase in PI of ≥ 24% identified responders with a sensitivity of 61% and a specificity of 74% (Fig. 2). The area under the ROC curve was 0.68.

In contrast to the study's hypothesis, PVI did not show significant differences between fluid responders and non-responders.

**Conclusions:** This study provides evidence supporting the use of PI as a non-invasive metric for predicting fluid responsiveness during PLR in spontaneously breathing post-surgical patients.

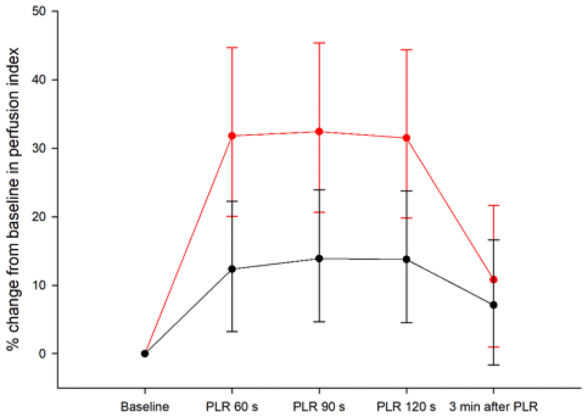

**Fig. 1 (abstract 001577)** Percentage changes from baseline in perfusion index (PI) during (at 60 s, 90 s and 120 s) and three minutes after the passive leg raising (PLR) test, subdivided between responders (red colour) and non-responders (black colour)

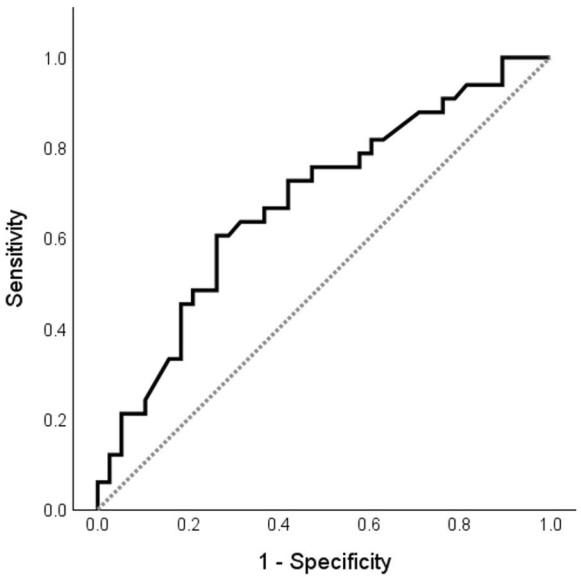

**Fig. 2 (abstract 001577)** Area under the receiver operating characteristics (ROC) curve generated to detect an increase of at least 10% in stroke volume by the relative changes in perfusion index

**Introduction:** As with so many aspects of modern medicine, the equations used to estimate glomerular filtration rate (eGFR) were not derived with critically ill patients in mind. Fundamental issues influencing the handling of creatinine in critical illness (fluid resuscitation, loss of muscle mass, systemic inflammation) mean intensive care physicians must remain cognizant of the limitations of creatinine-derived eGFR. Cystatin C is increasingly recognised as an alternative for GFR estimation on ICU [1].
Perhaps one of the biggest implications of inaccurate GFR estimation is upon medication dosing. Antibiotics and anticoagulants are examples of common medications frequently dosed with respect to kidney function in the ICU.
**Objectives:** We undertook a proof-of-concept study to compare the performance of creatinine and cystatin C-derived eGFR equations against gold-standard iohexol-measured GFR (mGFR) in adult ICU patients where creatinine may be unreliable.
**Methods:** '*In*patient adoption of *Cyst*atin C eGFR in guiding patient management' (InCyst study) (REC: 22/LO/0560) had the following inclusion criteria for ICU patients:

- serum creatinine below the lower limit of the reference range
- body mass index < 18 kg/m$^2$
- mechanical ventilation with > 10% fall in creatinine (in the absence of AKI recovery)
- AKI recovery where eGFR-dependent changes to drug dosing could be required

Timed blood collections were taken over the course of 24 h following a 5ml bolus of iohexol to determine mGFR. In addition, serum creatinine and cystatin C were measured and eGFR was calculated using multiple validated equations including MDRD, CKD-EPI 2021 (creatinine), CKD-EPI 2021 (cystatin C) and CKD-EPI 2021 (combined).
Bland–Altman bias (mean of differences) and precision (standard deviation of differences) was calculated for each equation to assess performance. The proportion of results within 30% (p30) and 10% (p10) of mGFR was also determined.
**Results:** Twenty patients were recruited in total, 12 were male. Mean age was 54 (± 14)years, mGFR was 76 (± 32)mL/min/1.73m$^2$, BMI 25.7 (± 6)kg/m$^2$, and length of stay 9 (± 6)days.
The best-performing eGFR equation against mGFR was CKD-EPI 2021 (cystatin C): bias − 0.71 mL/min/1.73m$^2$, precision 27mL/min/1.73m$^2$ and p30 61%. All creatinine equations performed badly, the currently internationally recommended equation CKD-EPI 2021 (creatinine) having a bias of 114mL/min/1.73m$^2$, precision 120mL/min/1.73m$^2$ and p30 of just 17%. Full performance of all equations is found in Table 1, illustrated in Fig. 1.
InCyst also reiterated the heterogenous, non-linear relationship between creatinine, BMI and GFR in ICU, demonstrated graphically in Fig. 2.
**Conclusions:** Within the limitations of a small sample size, this study demonstrates that creatinine is not a reliable biomarker of kidney function in the ICU. More accurate biomarkers must be sought to ensure accurate drug dosing. Cystatin C is a more viable candidate and there may yet prove to be a role for mGFR in high-risk cases, perhaps with the use of finger prick iohexol analysis, which has shown promise in the outpatient setting [2].

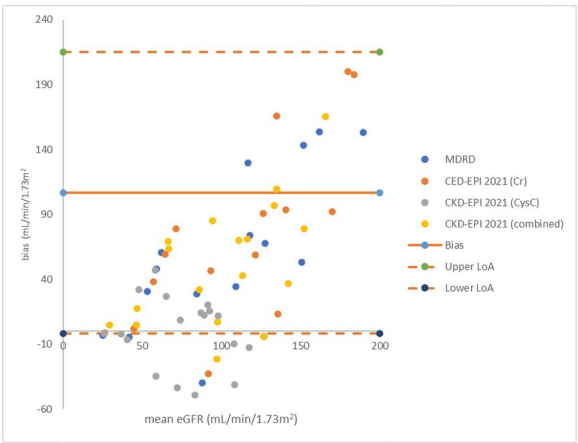

**Fig. 1 (abstract 001579)** Bland–Altman plot assessing the performance of different GFR estimating equations

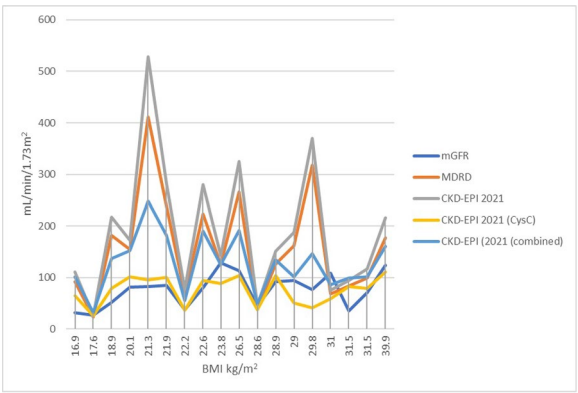

**Fig. 2 (abstract 001579)** Graphical comparison of mGFR and eGFR against different patient BMI values in InCyst

**Table 1 (abstract 001561)** Bias, precision, p30 and p10 of GFR estimating equations compared against iohexol mGFR.

| Equation | Bias (mL/min/1.73m²) | Precision (mL/min/1.73m²) | p30 (%) | p10 (%) |
|---|---|---|---|---|
| CKD-EPI 2021 (cystatin C) | -0.71 | 27 | 61 | 17 |
| CKD-EPI 2021 (creatinine) | 114 | 120 | 17 | 11 |
| CKD-EPI 2021 (combined) | 52 | 47 | 33 | 11 |
| MDRD | 83 | 94 | 17 | 6 |

### Psychosocial support on ICU: a post-discharge patient survey

D. Cottam[1], M. Santi[1], V. Metaxa[1]
[1]Intensive Care Medicine, King's College Hospital, London, United Kingdom
**Correspondence:** D. Cottam
***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001581

**Introduction:** Psychological, cognitive and functional difficulties are common post intensive care unit (ICU) admission, with up to 50% of patient's experiencing long-term psychological morbidity [1]. Adequate social support in ICU is associated with improved mental health and long-term outcomes [2]. In our ICU there is a psychosocial team (P-S team), comprising a psychiatrist, two psychologists and one social worker. Their primary aim is to support patients and their families with psychological and social (including accommodation and financial) issues encountered during intensive care admission.
**Objectives:** To evaluate patients' experience of the P-S team during ICU admission, as well as their self-reported psychological, social and physical support needs post-ICU discharge.
**Methods:** Over 2 separate 7-day periods, patients discharged from ICU were screened for eligibility, excluding patients admitted for < 72 h. Reason for admission, discharge specialty, length of ICU stay, discharge GCS and any recorded P-S team input were recorded. Patients were reviewed on the ward within 48 h of discharge and if appropriate were asked to complete a 6-part questionnaire, evaluating the input of the P-S team, and their psychological and physical support needs post ICU discharge.
**Results:** Of the 71 patients discharged during the study period, 35 were excluded (9 deceased, 26 admitted < 72 h). Demographic data of the 36 included patients are shown in Table 1. 14 patients (39%) had P-S team input prior to ICU discharge. The follow-up questionnaire was completed by 25/36 patients (69%), of which 9 received input in ICU; 6 out of those 9 patients (67%) reported finding this input helpful. Further support post-ICU discharge was desired by 11/25 patients (44%), predominantly psychological support (7 patients). 88% of patients (22/25) experienced at least 1 of low mood, mood swings, anxiety, fatigue, intrusive thoughts or feelings of hopelessness post discharge. Of those, 5 patients (23%) felt that further P-S team input would be helpful. Only 10 patients (10/25, 40%) were self-caring post discharge and 21/25 (84%) reported a change/reduction in their mobility since ICU discharge. Reduced satisfaction with medical and nursing staff communication post discharge was reported by 8/25 patients (32%). The majority (22/25, 88%) reported good social support from friends/family.

**Table 1 (abstract 001581)** Demographics

| | All | Completed questionnaire |
|---|---|---|
| | ***n*** **(%)** | ***n*** **(%)** |
| *Gender* | | |
| Male | 18 (50) | 10 (40) |
| Female | 18 (50) | 15 (60) |
| *Age (years)* | | |
| | Median 58.5 | Median 59 |
| | Range 16–89 | Range 16–89 |
| *Admission type* | | |
| Medical | 21 (58) | 15 (60) |
| Surgical | 10 (28) | 9 (36) |
| Trauma | 2 (6) | 1 (4) |
| Neurosurgical | 3 (8) | 0 |
| *Length of stay (days)* | | |
| | Median 11 | Median 11 |
| | Range 4–49 | Range 4–42 |

**Conclusions:** Psychosocial team input in the ICU was welcomed by the majority of the patients surveyed. More than 80% reported a

physical decline and approximately half had ongoing unaddressed psychological and physical support needs. Given the current financial constraints, a way to continue supporting patient recovery following ICU admission is needed.

### Beta-lactam antibiotics exacerbate features of sepsis-induced immunosuppression in vitro

H. Kim[1], S. Charoenpong[1], J. Boyu[1], T.A.C. Snow[1], K. Carthigesan[1], A. Cesar[1], F. Ryckaert[1], N. Saleem[1], A.V. Waller[1], M. Singer[1], S. Elkhodair[2], D. Brealey[3], N. Arulkumaran[1]

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001582

**Introduction:** Antibiotics are known to modulate the immune system. [1, 2] We hypothesised that beta-lactam antibiotics may exacerbate features of sepsis-indued immunosuppression. This may indeed paradoxically increase the risk of secondary infections.

**Objectives:** To identify if amoxicillin, cefuroxime, meropenem or piperacillin alter the response of monocytes and lymphocytes to a bacterial stimulus in vitro.

**Methods:** Blood was collected and peripheral blood mononuclear cells (PBMCs) were isolated from patients presenting to the emergency department with infections ($n = 10$). PBMCs were incubated with LPS for 24 h (to assess monocyte function) or CD3/ CD28 beads for 48 h (to assess lymphocyte function) in the presence or absence of either amoxicillin, cefuroxime, meropenem or piperacillin-tazobactam. Clinically relevant doses of antibiotics were selected to represent the lower and higher levels of antibiotics measured in patients with critical illness. [3] We assessed the immunophenotype of cells using multicolour spectral flow cytometry. Data are presented as relative change (ratio) of median intensity fluorescence (MFI) between antibiotic-treated stimulated PBMCs and stimulated PBMCs without antibiotics.

**Results:** Broad-spectrum beta-lactam antibiotics were associated with more changes than narrow-spectrum beta-lactams. There were few changes consistent with a pro-inflammatory phenotype in classical monocytes (increased TLR-4 and CD80), although most changes were consistent with immunosuppression (reduction in NOX-2 and antigen presentation pathway proteins (CIITA, HLA-DR, HLA-DP, HLA-DM, CD74) NLRP3, NF-κB, and IL-1β). Similarly, in CD4 + lymphocytes, a phenotype consistent with immunosuppression (increased IL-4, CTLA-4, IL-10 and reduced IL-2, IL-17A) with reduced chemotaxis markers (CD194 and CD196) were induced by beta-lactam antibiotics. Similar changes were seen in CD8 + lymphocytes.

**Conclusions:** We show ex vivo evidence of beta-lactam-induced immunosuppression in monocytes and lymphocytes from patients presenting to the emergency room with infections. The in vivo effect in ICU patients needs to be determined. This highlights the potential merits of therapeutic drug monitoring, and antimicrobial stewardship (including limiting the duration of antimicrobial therapy and use of broad-spectrum antibiotics) in critically ill patients.

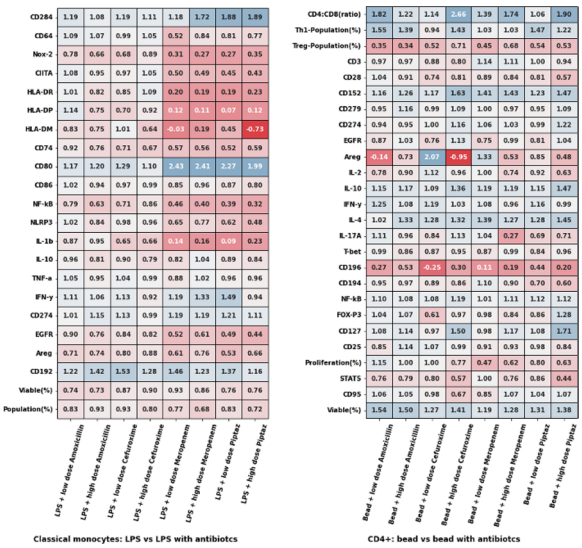

**Fig. (abstract 001582)** Beta-lactam antibiotics induce a broad immunosuppresive phenotype in stimulated classical monocytes (left) and CD4 + lymphocytes (right). Data expressed as ratio change

### Setting optimal positive end-expiratory pressure based on lung ultrasound and static measurements of mechanical ventilation

**in critically ill patients with acute respiratory distress syndrome and acute brain injury**

T. Schizodimos[1], P. Ioannidis[1], G. Gkogkos[1], E. Papadopoulou[1], M.C. Grammenou[1], E. Kerezidou[1], G. Katsikaki[1], C. Iasonidou[1], G. Pitsiou[2]

**Correspondence:** T. Schizodimos
***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001584

**Introduction:** A common complication of patients with severe acute brain injury (ABI) is acute respiratory distress syndrome (ARDS) associated with increased mortality and poor neurological outcome. The application of positive end-expiratory pressure (PEEP) during mechanical ventilation (MV) has been recognized as beneficial in patients with ARDS. In addition to static measurements of MV, lung ultrasound (LUS), a non-invasive imaging method of lung parenchymal abnormalities, could help in determining the optimal PEEP.
**Objectives:** To investigate the utility of LUS and static measurements of MV in determining optimal PEEP in critically ill patients with ARDS and ABI.
**Methods:** A preliminary, interventional, prospective clinical study was performed in a Greek ICU, including 16 patients with ABI (6 TBI, 3 SAH, 7 ICH) and ARDS. GCS on admission, APACHE II and LISS score were recorded. The intervention included a gradual increase in PEEP level from 5 to 8, 12 and 16 cmH2O. After each PEEP level change we performed LUS in 6 regions in each lung and calculated the LUS score. Simultaneously, static MV parameters [plateau pressure (Ppl), driving pressure (ΔP), static compliance (Cst)] and PaO2/FiO2 ratio (PFR) were recorded. During these maneuvers, we ensured normal ICP and adequate CPP in all patients, as measured via an intraparenchymal catheter.
**Results:** Included 16 patients had a mean age of 56.3 (0SD ± 17.5) years, mean ICU admission GCS of 6.8 (SD ± 2.83), mean APACHE II score of 20.1 (SD ± 3.77) and mean LIS score of 2.02 (SD ± 0.42). There was a statistically significant difference in LUS score regarding all PEEP pairs (Table 1).

**Table 1 (abstract 001584)** LUS score comparison between PEEP levels

| PEEP level pairs | *p* value |
|---|---|
| PEEP 5/PEEP 8 | 0.031 |
| PEEP 8/PEEP 12 | 0.004 |
| PEEP 12/PEEP 16 | 0.004 |
| PEEP 5/PEEP 12 | 0.003 |
| PEEP 5/PEEP 16 | 0.003 |
| PEEP 8/PEEP 16 | 0.003 |

As PEEP level increased, a progressive decrease in LUS score (Fig. 1) and a continuous increase in PFR (Fig. 2) were observed, whereas we could not detect a uniform pattern of change in ΔP or Cst value (Figs. 3,4). The lowest PEEP level with the lowest LUS score was compared with the lowest PEEP level with the best PFR, and there was no significant difference in PEEP according to LUS or PFR (Table 2).

**Table 2 (abstract 001584)** Comparison of optimal PEEP according to LUS and PFR

| Variable | PEEP (LUS) | PEEP (PFR) | *P* value |
|---|---|---|---|
| Median (IQR) | 16 (IQR 16–16) | 16 (IQR 15–16) | 0.134 |

We also explored the relationship between PEEP with maximum PFR and PEEP with the safest ΔP or Ppl. The difference between safe PEEP levels according to ΔP or Ppl and PEEP with the best oxygenation was not significant (Tables 3,4).

**Table 3 (abstract 001584)** Comparison of selected PEEP according to PFR and ΔP

| Variable | PEEP (PFR) | PEEP (Δ*P*) | *P* value |
|---|---|---|---|
| Median (IQR) | 16 (IQR 15–16) | 16 (IQR 16–16) | 0.41 |

**Table 4 (abstract 001584)** Comparison of selected PEEP according to PFR and Ppl

| Variable | PEEP (PFR) | PEEP (Ppl) | *P* value |
|---|---|---|---|
| Median (IQR) | 16 (IQR 12–16) | 12 (IQR 12–16) | 0.621 |

Maximum oxygenation could be achieved without worries about exceeding Δ*P* or Ppl safety limits. When comparing the lowest PEEP level—lowest LUS score with the maximum PEEP level—lowest Δ*P* or Ppl, we found that LUS can be used to set the PEEP level without reaching unsafe Δ*P* values, in contrast to Ppl. Finally, there was a significant deviation in PEEP according to lung ultrasound and Cst.
**Conclusions:** LUS could be used to set the PEEP level that ensures the best oxygenation, i.e. the optimal PEEP, in patients with ABI and ARDS. In contrast, static measurements of MV did not appear to be helpful in this field, except in terms of safety.

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001585

**Introduction:** Early microbiologic diagnosis and appropriate antibiotic initiation increase survival in intensive care unit infections and sepsis. The basic approach in treatment is to initiate empirical antibiotic therapy after cultures are obtained. Considering the prevalence of multidrug resistance, rapid microbiologic diagnosis and selection of antibiotic therapy according to the resistance pattern is of vital importance. In this context, it is possible to contribute to the treatment process by rapid microbiological diagnosis and resistance gene analysis with m-PCR (multiplex PCR) rapid diagnostic tests. In this study, the diagnostic compatibility and speed of the m-PCR method compared to the conventional method were investigated.
**Methods:** After obtaining ethics committee approval, the data of patients followed up in the intensive care unit between October 2022 and October 2023 due to infection were analyzed retrospectively. Blood cultures and m-PCR from the patients were designed and the data of the patients who were interned in the General Intensive Care Unit of Yeditepe University were used in the study. The results of blood cultures and m-PCR tests, signal and notification times, blood culture and m-PCR results, compatibility, and resistance genes, if any, were recorded. The results were statistically evaluated and $P < 0.05$ was considered statistically significant.
**Results:** Data from a total of 40 patients were used in the study. The gender distribution of these patients was 57.5% male (23) and 42.5% female (17). The median age was 63.5 years and the microorganism distribution in the m-PCR results was as follows: s.epidermidis 42%, e.faecalis 15%, *p*.aurogineosa 12.5%, a.baumanii 19%, streptococcus spp 10%, e. coli 7.5%, stapylococcus spp 7.5%, k.pneumonia 5%, c.albicans 2.5%, c.tropicalis 2.5%, *p*.vulgaris 2.5%, e.clocae 2.5%, k.oxytoca 2.5 2.5%. The concordance of the rapid test with the culture result was 97.5%. The median rapid test result time was 77.5 min, the median culture result time was 4.91 days and the mean was 4.37 days.
**Conclusions:** The results of m-PCR and blood culture were found to be highly compatible in this study. In this context, it can be predicted that the m-PCR test is safe to use and can be used safely due to its rapid results, which is useful both for the rapid initiation of appropriate antibiotherapy and for the prevention of multiple antibiotic resistance. Further studies on the subject should be conducted and the test should be widely used.

**Topic:** Infections and prevention

**Introduction:** The intermediate care unit bridges conventional hospitalization and the intensive care unit (ICU), acting as a step-up and step-down facility and serving as a strategic ICU in crises. This unit is distinguished by its intensive nursing care, monitoring equipment, respiratory support, and the expertise of its healthcare professionals.
**Objectives:** The study aims to better understand the evolution of the intermediate care unit and its implications on patient care.
**Methods:** Retrospective descriptive study of the activity in a multipurpose intermediate care unit managed by the Intensive Care Department of a university hospital. Patient records from 2018 to 2023 were collected and analyzed, including demographic variables (sex and age) and activity-related variables (origin, length of stay, diagnosis, and discharge destination).
**Results:** During the study period, 10,119 patients were admitted to the Intensive Care Department, of which 7382 (72.9%) were admitted directly to or stayed in the intermediate care unit. The majority were males (63.9%) with an average age of 58.42 ± 15.30 years. 28.9% of admissions came from the ICU. The diagnostic groups at admission included postoperative patients of neoplastic processes (24.9%), followed by cardiac cases (19%) with a predominance of acute coronary syndromes (86.8% of cardiac cases), septic processes (7.5%), and traumatic patients (6%), predominantly those with associated traumatic brain injury (54.8% of the group). The semi-critical care unit was the final discharge unit for 1839 patients (24.9% of those admitted), with 20 voluntary discharges/evasions, 134 deaths, and 1684 final discharges (35.4% transferred to other centers and 1087 discharged home with follow-up care).
**Conclusions:** The variety of patients treated and discharged with follow-up care underscores the complexity and highlights the need for a wide range of resources and knowledge to provide adequate care. Multipurpose intermediate care units play a strategic role in the healthcare system.

**Introduction:** Extracorporeal cardiopulmonary resuscitation (ECPR) is a rescue therapy for refractory cardiac arrest. The initial phase of ECPR requires fluid loading and vasopressor support to provide adequate blood flow and optimal tissue perfusion. The present study aimed to compare two different fluid resuscitation strategies in a porcine model of refractory cardiac arrest supported by veno-arterial extracorporeal membrane oxygenation (ECMO).
**Methods:** Fourteen pigs were submitted to 15 min of untreated ventricular fibrillation followed by 30 min of ECPR in normothermia. Defibrillations were then delivered until the return of spontaneous beating (ROSB). Animals were followed for 120-min after ROSB with ECMO flow set at 35 mL/kg/min and the sweep gas flow titrated to maintain normocapnia. At the beginning of ECPR, we randomly assigned pigs into two groups: restrictive strategy (group R, $n = 7$) or liberal strategy (group L, $n = 7$). In both groups, the same mean arterial pressure (MAP) was targeted at the value of 65–70 mmHg with different fluid loading strategies. In the R group, pigs were given fluid (Ringer's lactate) at 15 mL/kg during ECPR followed by 15 ml/kg/h after ROSB. In the L group, fluids were administered to target the minimal MAP value, while maintaining right atrial pressure (RAP) below a safety limit of 18 mmHg. If ECMO alone was not able to reach the MAP value, epinephrine bolus and norepinephrine infusions were administered during ECPR and after ROSB, respectively. Measurements included intracranial pressure (ICP), cerebral vascular resistances (CVR), native cardiac output measured by echography and intra-abdominal pressure (IAP) monitored by bladder pressure. After the experiment, organs were sampled and edema was measured using the wet/dry (W/D) weight ratio for brain, heart, lungs, kidneys and small bowel.
**Results:** During this study, MAP target was maintained adequately throughout the follow-up and, as expected, the R group received a significantly lower cumulative volume of fluid as compared to the L group (44 ± 2 ml/kg vs 157 ± 3 ml/kg, respectively). This was associated with a significantly higher heart rate and a trend toward higher vasopressor dose throughout the follow-up in the R group, as compared to the L group. Intra-abdominal pressure was also significantly lower in the R group at the end of the follow-up (10 ± 1 vs 19 ± 5 mmHg in R and L groups, respectively). R group presented a significantly lower RAP and ICP values throughout the ROSB period, a trend toward a lower CVR and a lower native cardiac output as compared to the L group. Regarding organ edema, there was a trend to decreased W/D ratio measures in the R group compared to the L group for lung, heart and small bowel (27.5 ± 5.2% vs 36.7 ± 11.8%, 27.3 ± 3.5% vs 33.4 ± 3.9% and 19.6 ± 3.0% vs 26.1 ± 3.9%, for each organs, respectively).
**Conclusions:** During early ECPR, liberal fluid resuscitation resulted in a detrimental increase in cerebral vascular resistance, ICP and RAP with tissue edema potentially leading to organ damage.

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001588

**Introduction:** Sepsis is one of the leading causes of Intensive Care Unit (ICU) and hospital admission worldwode. It is now increasingly recognised that admission with sepsis is associated with a long-term risk of adverse cardiovascular events.1 Many survivors of critical illness are burdened with significant functional impairments following admission.2 It is not clear whether cardiac dysfunction might play a role in these impairments and if so, what mechanisms might mediate this phenomenon. Here we present some early results from CONDUCT-ICU, a pilot, prospective observational cohort study combining cardiac magnetic resonance (CMR) imaging, biomarkers and functional outcome measures in ICU survivors of sepsis.

**Objectives:** To assess the prevalance of left ventricular systolic dysfunction following ICU admission with sepsis and the relationship with biomarkers of cardiovascular dysfunction and patient-reported functional outcome measures.
**Methods:** Patients recovering from sepsis with no prior history of cardiovascular disease are approached and consented around the point of discharge from intensive care. Cardiac and inflammatory biomarkers were collected at recruitment and if not undertaken already, a focused echocardiogram was performed. Patients are followed up 6–10 weeks following discharge from the hospital where CMR imaging is undertaken in addition to the collection of patient-reported outcome measures and inflammatory and cardiac biomarkers (Fig. 1). The primary outcome of the study is the prevalence of abnormal left ventricular systolic dysfunction (LVSD). After the successful follow-up of 15 patients, we conducted an interim analysis to ensure the operational integrity of the methodology.
**Results:** 20 survivors of sepsis were recruited for CMR follow-up and 15 attended their follow-up visit. Of those that underwent CMR scanning, a high proportion (4/15 (26%)) of patients had LV systolic dysfunction. Patients with LVSD had a median LV ejection fraction (LVEF) of 39% (IQR 36–42). Median NT-pro BNP on discharge was 1474 pg/ml (IQR 190–6326) and Trop T value of 18 pg/mL (IQR 13–50), which reduced on the follow-up visit, but remained abnormal at 126 pg/ml (IQR 78–185) and 14 pg/ml (IQR 8–20), respectively. Patients with LVSD had a higher median NT-proBNP in comparison to those without (169 pg/ml (IQR 37–158) vs 126 pg/ml (IQR 115–448) $p$ 0.4) and rated their overall health as worse when measured in EQ-5D-5L visual analogue scale (28 vs (24–39) vs 60 (IQR 54–90)). Patients with diabetes had a significantly lower ejection fraction vs those without (40% vs 57%, $p$ 0.05).
**Conclusions:** Early interim analysis of participants in CONDUCT-ICU demonstrated the feasibility of our research protocol. In the first 15 participants, admission with sepsis was associated with a high prevalence of LV dysfunction that persists weeks beyond discharge from the hospital. The study will give key pilot data to inform larger studies and give insights into mechanisms of adverse cardiovascular risk following ICU admission with sepsis.

**Introduction:** Acute brain injury (ABI) of any etiology is associated with significant mortality and disability worldwide. Depending on the severity of the injury, the patient with ABI may require intubation and hospitalization in the intensive care unit (ICU). Various prognostic indices, such as the Charlson comorbidity index (CCI), Glasgow coma scale (GCS) on ICU admission and APACHE II score, could be used to predict the outcomes in this patient population.
**Objectives:** To investigate the relationship of CCI, ICU admission GCS and APACHE II score with mortality and 6-month neurological outcome in patients with ABI.
**Methods:** A retrospective data analysis was performed in a Greek level 3 ICU. We collected data from a total of 94 critically ill patients with ABI of any etiology (40.4% traumatic brain injury, 27.7% subarachnoid hemorrhage, 28.7% intracerebral hemorrhage, 3.2% ischemic stroke). Demographic and baseline data, ICU admission GCS, CCI and APACHE II score during the first 24 h were calculated and recorded. Simultaneously, we recorded in-ICU mortality, mortality at 28 days, 3 and 6 months, and neurological outcome at 6 months using the Glasgow outcome scale extended (GOS-E).
**Results:** Included 94 patients were males in 61.7%, had a median age of 61 (IQR 49.25–67.75) years, median CCI 2 (IQR 1.00–3.75), median ICU admission GCS 7 (IQR 4.25–9.75) and mean APACHE II score 18.77 (SD 6.11). The mortality rate in ICU, at 28 days, 3 and 6 months was 28,7%, 35.1%, 48.9% and 55.3%, respectively. We observed that a higher CCI score was related to increased mortality and this was more pronounced in long-term follow-up (Fig. 1). It was evident that a higher GCS on ICU admission significantly favored survival at all time points ($p < 0.001$) (Fig. 1). Higher mortality was observed in patients with increased APACHE II score at all time points, particularly in long-term follow-up (Fig. 1). Regarding neurologic outcome, we found that a higher GCS on ICU admission was moderately associated with better GOS-E at all time points ($p < 0.001$) (Fig. 2). An increased comorbidity burden based on CCI showed a moderate association with worse recovery at follow-up ($p < 0.001$) (Fig. 2). Finally, increased APACHE II score was moderately associated with lower GOS-E at follow-up ($p < 0.001$) (Fig. 2).
**Conclusions:** CCI, ICU admission GCS and APACHE II score are useful predictors of outcome in critically ill patients with ABI. Increased CCI or APACHE II score and decreased GCS seem to be associated with both increased mortality and worse neurological outcomes in this patient population.

### Agreement between central venous catheter and pulmonary artery catheter-derived perfusion markers in a swine model of cardiogenic shock

A. Picod[1], F. Manicone[2], F. Su[3], F.S. Taccone[4], A. Herpain[5]
[1]Experimental Laboratory of Intensive Care, Université Libre de Bruxelles, Bruxelles, Belgique, INSERM, Brussels, Belgium, [2]Experimental Laboratory of Intensive Care, Université Libre de Bruxelles, Bruxelles, Belgique, Sapienza University of Rome, Roma, Belgium, [3]Intensive Care, Hospital Erasme, Bruxelles, Belgium, [4]Soins Intensif, ULB Erasme, Anderlecht, Belgium, [5]Department of Intensive Care, Université Libre de Bruxelles, Bruxelles, Belgium

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001590

**Introduction:** Venous oxygen saturation and veno-arterial CO2 pressure gradient are pivotal variables to guide resuscitation in cardiogenic shock patients and thus are routinely measured in experimental models (1). Initially, these variables were described from coupled arterial and pulmonary artery catheter (PAC) samplings. However, clinicians increasingly compute these variables using a less invasive central venous catheter (CVC), rather than a PAC, although the agreement between the two sampling sites remains elusive.
**Objectives:** To assess the agreement between CVC and PAC-derived measures of venous oxygen saturation and veno-arterial CO2 pressure gradient pre-, per- and post-experimental acute myocardial infarction-related cardiogenic shock (AMI-CS).
**Methods:** In adult swine under deep general anesthesia, AMI-CS was induced by critical endovascular sub-occlusions of proximal left anterior descending and mid-circumflex coronary arteries for two hours. Animals were then resuscitated for a total of 9h30 by several therapeutic regimens (vasoactive drugs, and/or veno-arterial extracorporeal membrane oxygenation [VA ECMO], and/or an anti-DPP3 antibody). Instrumentation included an arterial catheter, a CVC with the tip positioned at the level of the superior vena cava-atrial junction, and a PAC. At each time point, samples extracted from these catheters within a 5 min delay from each other's, were used to compute venous oxygen saturations (ScvO2/SvO2) and veno-arterial CO2 pressure gradients (Pcv-aCO2/Pv-aCO2). Spearman rank correlation and agreement according to the Bland–Altman method between paired measurements were evaluated.
**Results:** Data from 11 pigs including 55 paired measures of both venous oxygen saturation and veno-arterial CO2 pressure gradient were included in this preliminary analysis. Induction of myocardial ischemia was associated with a reduction of cardiac output (− 43% from 6.9 to 3.9 L/min), mean arterial pressure (− 23% from 71 to 55 mmHg) resulting in perfusion impairment reflected by ScvO2/SvO2 decrease and Pcv-aCO2/Pv-aCO2 increase (Fig. 1A/B). Good correlation was observed for ScvO2/SvO2 ($rs = 0.82$; $p < 0.0001$), whereas moderate correlation was reported for Pcv-aCO2/Pv-aCO2 ($rs = 0.51$; $p < 0.0001$) (Fig. 1C/D). The ScvO2 overestimated the SvO2 by a mean bias of 6.35% ± 7.15% while the 95% limits of agreement were wide, from − 7.65 to 20.36%. The Pcv-aCO2 overestimated the Pv-aCO2 by a mean bias of 1.71 mmHg ± 3.69 mmHg with 95% limits of agreement from − 5.52 mmHg to 8.93 mmHg. Similar results were found independently of the resuscitation strategy (notably animals treated by VA ECMO or not) or the timepoint considered.
**Conclusions:** In a large animal model of AMI-CS the agreement between the venous oxygen saturations or veno-arterial CO2 pressure gradients computed with venous samples extracted from CVC or PAC was poor. Therefore, these two sites cannot be used interchangeably, and the use of PAC-derived measurements should be preferred as they depict the whole body oxygen delivery adequacy (1).

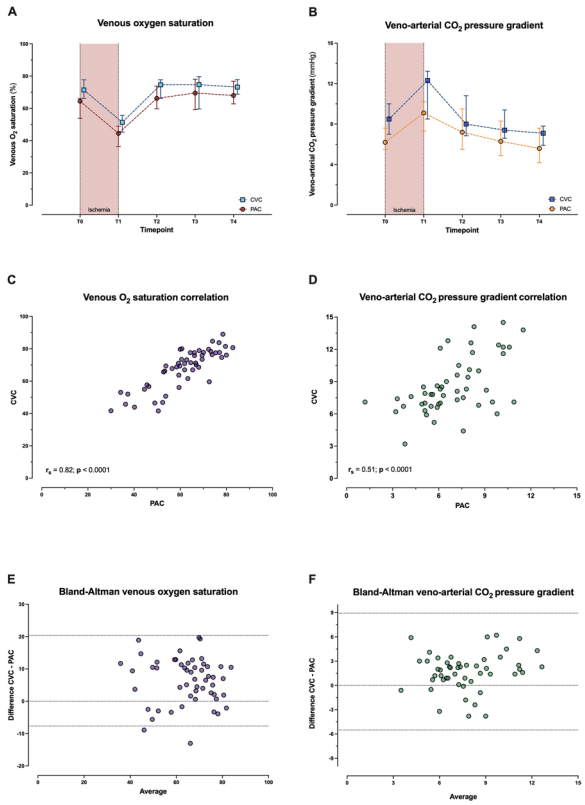

**Fig. 1 (abstract 001590)** Timecourse of venous oxygen saturation (A) and veno-arterial CO2 pressure gradient (B), correlation (C and D), and Bland–Altman agreement between values measured from CVC and PAC (E and F). CVC: central venous catheter; PAC: pulmonary artery catheter. T0: baseline, T1: end of ichemia; T2: after 1h30 of resuscitation; T3: after 5h30 of resuscitation, T4: after 9h30 of resuscitation

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001591

**Introduction:** During acute lung injury, ventilation-perfusion (V/Q) mismatching drives hypoxemia (1). Hypoxic pulmonary vasoconstriction (HPV) plays a crucial role in modulating the V/Q ratio to sustain oxygenation. The effect of HPV depends on the local oxygen tension in the lungs as well as the constriction capability of the pulmonary vasculature, which may vary between direct lung injury from the alveolar side and indirect lung injury from the endothelial side (2,3). Electrical impedance tomography (EIT) enables bedside monitoring of regional ventilation and perfusion, facilitating the investigation of their response to different lung injury models. Additionally, it helps to explore the interaction between regional perfusion and ventilation dynamics, as well as variations in oxygenation (4).
**Objectives:** To compare the effects of pulmonary injury induced by intratracheal hydrochloric acid (HCl) and extrapulmonary injury induced by intravenous oleic acid (OA) on ventilation and perfusion distribution in acute lung injury animal models.
**Methods:** In a prospective study (ethics No. 20/3464), nineteen experimental hypoxemic acute lung injury pigs were divided into HCL ($n=11$) and OA ($n=8$) groups. EIT, gas exchange, and ventilator settings were assessed before and after lung injury. Detailed methods can be found in a previous article (5). Dynamic changes in EIT ventilation and perfusion percentages were evaluated in three lung regions according to gravity (dependent, middle, non-dependent).
**Results:** Detailed results are summarized in Fig. 1 and Table 1. Following lung injury induction, both groups demonstrated decreased ventilation in the dependent and middle regions, alongside increased ventilation in the non-dependent region. Notably, the HCL group exhibited pronounced ventilation impairment in the dependent regions compared to the OA group. Furthermore, in both models, perfusion distribution mirrored ventilation changes rather than gravity, with the HCL group showing more significant increases in the non-dependent and middle regions, resulting in a higher proportion of areas with V/Q match and a higher PF ratio.
**Conclusions:** In the hypoxemic animal model, perfusion changes aligning with ventilation distribution post-injury, independent of gravity, suggest the involvement of HPV. Specifically, HCL induced a focused alveolar impact in the dependent region, whereas OA caused a more diffuse and homogeneous endothelial injury. Consequently,

the endothelial damage or less severe regional hypoxemia in the OA group may compromise HPV function, thereby exacerbating V/Q mismatch and deteriorating hypoxemia.

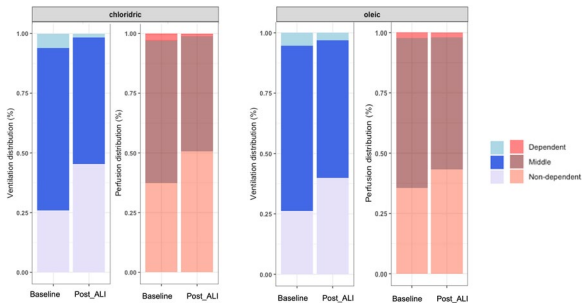

**Fig. 1 (abstract 001591)** Changes in regional ventilation (blue) and perfusion (red) distribution percentages in pulmonary (chloride) and extrapulmonary (oleic) hypoxemic experimental animal models. "Baseline" refers to values measured before lung injury, "Post_ALI" refers to values after lung injury induction

**Introduction:** Assessing and managing fluid status is a central challenge in caring for critically ill patients, especially those with septic shock. Estimated plasma volume status (ePVS) has recently emerged as a potential noninvasive method to assess volume status in the intensive care unit (ICU) and has been proposed as a biomarker associated with excess fluid balance and poor prognosis in acute heart failure, ARDS and septic shock. We aimed to assess the prognostic value of ePVS in septic shock patients admitted to the ICU.
**Methods:** Retrospective observational study conducted at a tertiary university hospital, including critically ill patients diagnosed with septic shock between September 2018 and February 2019. To estimate PVS Duarte's formula was applied at different time points in the first 96 h of ICU stay. Descriptive statistical analysis, including non-parametric tests, and regression analysis were performed as appropriate. Statistical significance was defined as a $p$-value < 0.05.
**Results:** We included 182 patients (114 males, 68 females) with a median age of 69 years (interquartile range [IQR]: 59–78) and a median SAPS II score of 62 (IQR: 46.2 − 76.0). ICU mortality was 49.5%. Patients who did not survive had higher mean ePVS during the first 48 h compared to survivors (day 0: 7.02 ± 2.67 dL/g vs. 6.23 ± 1.8 dL/g, $p = 0.02$; day 1: 7.20 ± 2.54 vs. 6.32 ± 1.86, $p = 0.01$). A sensitivity analysis determined a cut-off point above 6dL/g to be associated with ICU mortality (OR 1.9, 95% CI 1.02–3.41), $p = 0.04$). The cumulative fluid balance in the first three days was 2.4 (− 1.5–15.3), 1.8 (− 2.9–10.9), 1.0 (− 2.3–4.8) and 0.7 (− 3.3–4.7) liters. The ePVS was correlated with fluid balance only on the third day of ICU admission ($p = 0.03$).
**Conclusions:** ePVS in the first 2 days of ICU admission was associated with increased in-hospital mortality in this cohort of critically ill septic shock patients. Moreover, there was a correlation between ePVS measured at day 3 and the amount of intravenous fluid resuscitation administered in the first 48 h. Our study suggests a role for ePVS as an easy-to-calculate prognostic marker in patients admitted to the ICU with septic shock. Fluid overload is increasingly recognized as a decisive risk factor for adverse outcomes in sépsis. ePVS association with cumulative fluid balance and mortality should be confirmed and further research is warranted to validate our findings in larger prospective cohorts.

### SAPS II predictive performance in neurocritical patients: insights from a general mixed intensive care unit

T. Maia[1], R. Gomes Silva[1], M. J. Ferreira Da Silva[1], I. Aragão[1], C. Gonçalves[1]
[1]Unidade de Cuidados Intensivos Polivalente, UCIP, Centro Hospitalar Universitário de Santo António, ULSSA, Porto, Portugal

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001596

**Introduction:** Since its development in 1993, Simplified Acute Physiology Score II (SAPS II) has been widely used to assess illness severity and predict outcomes in intensive care unit (ICU) patients. Despite its widespread use and proven efficacy in diverse ICU populations, its utility in predicting outcomes for neurocritical patients remains uncertain.
**Objectives:** This study aims to analyze how accurately SAPS II predicts hospital mortality for acute neurocritical patients treated in a standard mixed ICU setting.
**Methods:** A retrospective analysis was conducted on data from 171 neurocritical care patients admitted to a single center, over an 18-month period. Mortality outcomes were assessed at hospital discharge. Logistic regression analysis was employed to ascertain the predictive strength of SAPS II for hospital mortality.
**Results:** The patient cohort had a median age of 64 years (IQR 50–74), a male predominance (63.28%, $n = 112$), with the majority requiring emergent neurointensive care. Hospital mortality was observed in 26.32% of cases, yielding a Standardized Mortality Ratio (SMR) of 0.71. Notably, SAPS II score exhibited significant differences between survivors and non-survivors (40 vs 60, IQR 30–51 vs 52–69; $U = 944.50$; $p < 0.001$). Furthermore, the score demonstrated very good discrimination (AUC = 0.833) and calibration power (Hosmer–Lemeshow chi-square = 3.722; $p = 0.881$), and the predictive power for hospital mortality in neurocritical patients was statistically significant ($p < 0.001$; adjusted odds ratio 1.117, CI 1.074–1.161).
**Conclusions:** While SAPS II has consistently shown a correlation with mortality at discharge in general ICU patients, its accuracy in neurocritical setting remains to be established. Our single-center study not only demonstrated very good discrimination and calibration power for SAPS II within a single-center neurocritical population, but also showed its significant predictive ability for mortality. These findings lay an important groundwork for future multicentric studies of higher quality, essential for further investigation and consolidate this relationship, bringing to discussion if SAPS II predictive power in neurocritical care is related to a specific type of patient.

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001597

**Introduction:** Neurobehavioral disorders (NBDs) are frequently observed as long-term consequences of traumatic brain injury (TBI) and may hamper patients' functional recovery. The most common NBDs may include impulsivity, irritability, verbal aggression, socially inappropriate behavior, self-centeredness, lack of awareness, emotional lability, low frustration tolerance, and lack of drive [1]. In literature, demographic (i.e., gender, age and education) and clinical variables (i.e., Post-traumatic Amnesia duration and Glasgow Coma Scale severity) have been explored as predictors of NBDs. Despite its responsibility in the etiopathology of TBI however, the role of Traumatic Axonal Injury (TAI) has been scarcely studied.
**Objectives:** This study explored how different variables, including the occurrence of TAI, could be associated with the development of NBDs. Secondly, we explored the correlation between the NBDs, patients' functional outcome, and community life participation measured by the Glasgow Outcome Scale Extended (GOSE) and the Community Integration Questionnaire (CIQ).
**Methods:** We included 54 patients (12 F, 42 M; mean age 46.1). All the patients underwent a neuropsychological, behavioral and psychological assessment. We collected clinical measures in the acute/subacute phase and functional measures in the chronic phase.
**Results:** The most frequent NBDs observed by the caregivers were anger/ difficulty controlling temper, impulsivity and irritability. The best predictors of these disturbances were: education, post-traumatic amnesia (PTA) and TAI and explained about one-third of the variability of NBDs (adjusted $R2 = 0.35$). A significant moderate negative correlation emerged between NBDs and GOSE ($r = -0.64$) and CIQ ($r = -0.71$), both $p < 0.001$.
**Conclusions:** We should closely monitor patients with lower education, longer PTA, and TAI because they will likely develop long-lasting NBDs that could be more manageable when a timely addressed.

### Contribution of electrocardiogram and echocardiography in severe cardiotoxic agent poisoning

M. Jemii[1], H. Ben Ghezala[2], M. Kharrat[1], A. Ben Jazia[1], N. Brahmi[1]
[1]Intensive Care, Centre D'assistance Médicale Urgente-CAMU, Tunis, Tunisia, [2]Critical Care Unit Mahmoud Yaacoub Emergency Medical Center, University of Tunis El Manar, Rommana, Tunisia

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001598

**Introduction:** The frequency of acute poisoning by cardiotropic agents has greatly increased in recent years. In severe cases, the mortality rate can be alarming and can exceed 10% [1]. Cardiotropic agents include not only anti-hypertensive treatments and conventional anti-arrhythmics but also other medicinal and non-medicinal substances [2]. Transthoracic echocardiography, coupled with a good interpretation of the electrocardiogram, could be an alternative method to invasive explorations for the investigation of haemodynamic failure in cases of serious cardiotropic intoxication.
**Objectives:** To evaluate the contribution of Transthoracic echocardiography in patients suffering from cardiotoxic agent poisoning and in whom the electrocardiogram has detected abnormalities.
**Methods:** This was an observational study with prospective data collection including all cases of serious intoxication with a cardiotropic product managed in an intensive care unit over the 6-month period (October 2023–March 2024). Serious cardiotropic intoxication was based on the circumstances of the accident (ingestion or exposure to a cardiotropic product), clinical signs presented by the patient and electrocardiographic abnormalities on admission.

**Results**: Fifty patients were included. The mean age was 32.5 ± 15.6 years, with a sex of 0.3. Sixteen patients (32%) were being treated for depression and eight patients (16%) had a history of drug addiction.
According to the Poisoning Severity Score, intoxication was severe in 28 (56%) and fatal in three (6%).
Drugs were involved in 35 cases (70%), mainly psychiatric treatments in 22 cases and antihypertensive treatments in 12 cases. One case involved theophylline intoxication. A non-drug substance was noted in 15 cases.
The average time between consultation and exposure to the toxic agent was 5 ± 3.8 h.
The mean heart rate was 89.8 ± 28.8 bpm, systolic blood pressure (111 ± 27.1 mmHg) and diastolic blood pressure (64.4 ± 19.7 mmHg). Shock was detected in fourteen cases (28%): it was cardiogenic ($n = 6$; 12%), vasoplegic ($n = 6$; 12%) and hypovolaemic in one case.
Sinus tachycardia was observed in 18 patients (36%), supraventricular tachycardia ($n = 3$), sinus bradycardia ($n = 7$; 14%), prolonged PR interval ($n = 6$; 12%), and Brugada syndrome in one patient.
Repolarisation disorders related to ST segment or T wave abnormalities were detected on 45 ECGs (90%) and a prolonged corrected QT was observed in thirteen cases (26%). Four patients had a membrane stabilising effect. Fifteen patients had elevated troponins on admission (30%).
Transthoracic echocardiography was performed at an average of 10.8 ± 4.25 h after intoxication. It was pathological in seven patients (14%), showing a collapsed LVEF and global hypokinesia consistent with toxic myocarditis.
Orotracheal intubation was indicated in 23 patients (46%) with an average intubation time of 3.4 ± 3.1 days, Norepinephrine in fourteen patients, combined with dobutamine in seven cases.
A follow-up ECG was performed at H24 after management, with normalisation ($n = 29$; 58%).
Follow-up of echocardiography, when it was abnormal, showed a significant improvement in LVEF and regression of global hypokinesia in 6 patients.
The analytical study showed that QT prolongation on electrocardiogram was associated with abnormalities on echocardiography ($p = 0.043$; OR = 5.03; 95%; CI = [0.95; 26.7]), elevated troponins were associated with a risk of having a pathological echocardiography ($p = 0.000$; OR = 1.87; 95%; CI = [1.17; 3.01]). The mortality rate was of 6% ($n = 3$).
**Conclusions:** According to our results, the electrocardiogram could play a key role in the initial diagnosis and monitoring of cardiac abnormalities. and that coupled with transthoracic echocardiography, these tools could optimise clinical outcomes and provide a better understanding of the aetiologies of a shock to reduce the associated morbidity and mortality.

*Intensive Care Medicine Experimental* 2024, **12 (suppl 1)**: 001599

**Introduction:** ECMO mechanical support implantation is an increasingly widespread technique in the management of patients with cardiogenic shock (1). However, infectious complications associated with these devices are considered a poor prognosis sign and a negative predictor of survival in critically ill patients (2). Nosocomial infection is a common complication, but current studies report inconclusive results about its incidence and impact (3).
**Objectives:** To describe infectious complications in patients with cardiogenic shock and mechanical support with VA ECMO.
**Methods:** Descriptive, observational, retrospective study from 2011 to 2022. All patients admitted to the ICU with cardiogenic shock and ECMO VA support were included. Personal history, severity scales, infectious complications and evolution in the ICU are collected. Qualitative variables are described with frequencies; quantitative variables with median and interquartile range.
**Results:** 140 patients were included, 91 males (65%) with a median age of 55 (43; 63) years. Nine patients (6.5%) were immunosuppressed prior to implantation. The most prevalent infections were ventilator-associated pneumonia (VAP) developed by 78 patients (56.5%), bacteremia in 27 (19.6%) and ECMO surgical wound infection in 8 cases (5.8%). Multidrug-resistant (MR) bacteria caused 17.94% of VAP and 25% of ECMO access point infections. The rest of the personal history, reason for ECMO implantation, complications and evolution in the ICU are shown in Table 1.
**Conclusions:** VAP, bacteremia, and surgical wound infection are the most frequent infections in our cohort. MR bacteria caused less than 15% of infectious complications.

**Table 1 (abstract 001599)** History, scales, reason for ECMO implant, ECMO access, infections, MR etiology and ICU evolution. MR: Multidrug-resistant; CRB: Catheter-Related Bacteremia; VAP: Ventilator-Associated Pneumonia; SW: Surgical Wound.

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001600

**Introduction:** Brain dysfunction in septic shock patients is a common condition among critically ill patients, and its presence is linked to heightened mortality rates and a greater likelihood of cognitive impairment among survivors. Although alterations in cerebral hemodynamics have been described in septic patients, the underlying cause remains poorly understood. We hypothesized that impairment of cerebral compliance might occur in patients with septic shock.
**Objectives:** To assess cerebral compliance in septic shock patients.
**Methods:** Prospective ongoing pilot study including septic shock patient's as defined by Sepsis-3 criteria, within 48 h from the diagnosis onset. Intracranial compliance was assessed by using a non-invasive tool (B4C: Brain4care Corp, São Carlos, Brazil), which provided the P2/P1 ratio and time-to-peak over 5-min recording. A P2/P1 ratio > 1.2 was considered altered, as well as a TTP > 0.3. Physiological and clinical data were also collected.
**Results:** Sixteen patients have been included so far. The median age was 66 (57–75) years, with 67% were male. The median sequential organ failure assessment (SOFA) at the time of examination was 10 (IQR, 7–13), the norepinephrine dose was 0.35 (0.15–0.48) mcg/kg*min, and 81% were on mechanical ventilation. The median value of the P2/P1 ratio was 1.16 (1.04–1.34); however, 6 patients (37.5%) presented altered P2/P1. In addition, the median TTP was 0.28 (0.19–0.28); 7 patients (43%) presented at least one altered value of these two indices.
**Conclusions:** During the early stages of septic shock, cerebral compliance was altered in almost 40% of patients. The association of such alterations with clinically relevant patients' outcome needs to be further evaluated.

**Introduction:** Ventilator-associated pneumonia (VAP) is a major challenge in children with severe bronchiolitis who require mechanical ventilation. However, its risk factors and pathogenesis remain poorly understood. This study investigates the influence of nasopharyngeal microbiota on VAP development among children with bronchiolitis attended in Paediatric Intensive Care Units (PICUs).
**Methods:** This prospective cross-sectional study included children < 24 months with bronchiolitis requiring mechanical ventilation for ≥ 5 days at the PICU of a tertiary referral Children's Hospital between June 2020 and January 2023. Epidemiological, clinical, and microbiological data were collected at admission. Nasopharyngeal microbiota was characterized by sequencing the 16S rRNA gene (V3-V4 region). Analyses included alpha- and beta-diversity, and differential abundance at the genus level. A Random Forest model incorporating differential abundant genera was built using 5 k-fold cross-validation.
**Results:** A total of 40 children were included, however, only 35 nasopharyngeal aspirates met quality criteria for microbiota analysis (52.2%; median 1.4 months [IQR 0.95–2.1]; 57.1% male). Among these, 8 patients (22.8%; 75.0% male) subsequently developed VAP, while 27 did not (77.2%; 51.9% male), with no significant age differences observed (median 1.1 months [IQR 0.7–1.8] vs 1.4 months [IQR 1.0–2.5], respectively; $p = 0.220$).
Alpha-diversity analysis showed no significant differences (Chao1 $p = 0.195$; Shannon $p = 0.226$). However, children who developed VAP showed a different microbiota composition (Adonis $p = 0.007$, R2 = 11.8%), enriched in *Moraxella*, *Amniculibacterium*, *Enterobacter*, and *Streptococcus,* and *the* absence of *Prevotella*. The Random Forest model achieved a good discriminatory power for predicting VAP (mean AUC 0.80; accuracy 0.86).
**Conclusions:** The nasopharyngeal microbiota could be a VAP development significant predictor in paediatric patients with bronchiolitis requiring mechanical ventilation.

**Introduction:** The concept of goal-directed therapy moves from identifying a physiological variable that effectively discriminates a desired outcome from an undesirable one. In this context, the physician should direct therapy towards achieving that "number" to improve long-term outcomes.
Twelve years ago, a seminal paper from Sorrentino et al. [1] defined 22 mmHg of Intracranial Pressure (ICP) as the best-discriminating ICP threshold between Good and Bad Outcomes in traumatic brain injury (TBI) patients. Although the original paper did not aim to identify a cut-off for treatment, subsequent guidelines [2–4] suggested that threshold as a goal of therapy.
**Objectives:** This study aims to identify in a cohort of patients treated in our Institution the ICP threshold that maximally differentiates between Good and Bad Outcomes.
**Methods:** We retrospectively enrolled all consecutive adult and pediatric patients admitted to our Intensive Care Units (ICU) from January 2013 to June 2022 (Ethic Committee approval number 303/20) with a diagnosis of TBI and an ICP monitoring longer than 4 h. Informed consent was waived. We gathered demographic data, severity indicators upon admission (including Glasgow Coma Scale, pupillary reflex, hypoxia, and hypotension at the crash scene), initial imaging results (assessed using the Marshall and Rotterdam scales), length of hospital and ICU stays, incidence of decompressive craniectomy, Glasgow Outcome Scale Extended (GOSE) scores at hospital discharge and one-year post-injury.
Outcome was categorized into Good Outcome (GOSE > 3) and Bad Outcome (GOSE score < 4). We collected ICP data from intraparenchymal catheters whose readings were stored in our electronic health record (sample frequency 0.0033Hz). The time series were manually filtered and resampled on a minute-by-minute basis using linear interpolation. Time series shorter than 60 min were disregarded. For each patient, we calculated the mean ICP during the monitoring period. The optimal ICP threshold was determined using sequential chi-square methods [1], both for the entire population and for subgroups, including patients under 17 years old, over 65, over 75, and female patients.
**Results:** We enrolled 263 patients. Table 1 shows admission, treatment, and outcome data in the general population and in the predefined subgroup. Fig. 1 represents the distribution of chi-square values across the ICP cut-offs within the predefined groups. The ICP threshold was around 23–25 in the general population and slightly higher in the pediatric one. A lower threshold was identified for older patients, while a clear ICP threshold could not be identified for female patients.

| Variable | General population | Age < 17 years | Age > 65 | Age > 75 | Female patients |
|---|---|---|---|---|---|
| Patients, *n* | 263 | 46 | 75 | 22 | 58 |
| Age | 46 (23–69) | 8 (2–12) | 71 (69–73) | 78 (77–81) | 50 (24–69) |
| Gender (male) | 205 (78.0) | 34 (73.9) | 42 (79.3) | 17 (77.3) | 58 (100) |
| None pupile reactive | 47 (17.9) | 14 (30.4) | 10 (19.6) | 4 (18.2) | 10 (17.9) |
| GCS, at admission | 7 (3–11) | 5 (3–7) | 7 (4–13) | 11 (4–14) | 6 (4–10) |
| Marshal CT | 5 (3–5) | 5 (2–5) | 5 (5–5) | 5 (5–5) | 5 (5–5) |
| Rotterdam Scale | 4 (3–5) | 3 (2–3) | 4 (4–5) | 3 (3–5) | 3 (3–5) |
| ICU length of stay | 19.0 (8.0–31.0) | 13 (5–41) | 21 (10–31) | 13 (8–26) | 23 (12–39) |
| Hospital length of stay | 28.0 (13.0–43.0) | 19 (11–47) | 25 (10–39) | 19 (10–35) | 33 (18–50) |
| Good Outcome | 128 (48.7) | 27 (58.7) | 11 (20.8) | 2 (9.1) | 29 (50.0) |

**Conclusions:** Our results confirm the data found by Sorrentino [1] with an ICP threshold between 22 and 25. Moreover, our results indicate a greater resilience to ICP elevation in younger patients and an opposite trend in older ones.

### Risk factors for acute kidney injury in patients undergoing ECMO therapy: a cross-sectional study comparing COVID-19 and non-COVID-19 cohorts

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001603

**Introduction:** ECMO therapy has played a crucial role in managing patients with severe hemodynamic dysfunction or acute respiratory failure who have not responded to conventional treatment (1), during the COVID-19 pandemic. COVID-19, which has claimed millions of lives, over 6.9 million deaths (2). AKI represents a significant complication in both COVID-19 patients and those undergoing ECMO therapy, potentially limiting the benefits of this treatment.
**Objectives:** Assessing the risk factors associated with AKI between those patients with and without COVID-19, to enhance risk stratification and ultimately optimize the management of ECMO patients, improving clinical outcomes and reducing AKI-associated morbidity.
**Methods:** This is a cross-sectional study between 2019 and 2023. A total of 273 patients who received ECMO therapy were included in the study, 110 were excluded due to either a lack of AKI development ($n=95$) or incomplete data ($n=15$). The final analysis included 163 patients, who were divided into two groups: COVID-19 patients ($n=27$) and non-COVID-19 patients ($n=37$). Demographic, clinical, and laboratory data were collected from electronic medical records retrospectively. Variables of interest included age, sex, comorbidities, severity of illness scores, ECMO-related variables, laboratory parameters, and development of AKI.
**Results:** Among the 163 patients managed with ECMO, who developed acute kidney injury, we compared risk factors for AKI development between COVID-positive and COVID-negative cohorts. Among COVID-19 patients, a higher proportion were male (85%), experienced longer durations of invasive mechanical ventilation (18.1 vs. 14.3 days), and spent more time on ECMO support (15.9 vs. 7.5 days). Complication analysis showed notable discrepancies in neurological (6 COVID-19 vs. 1 non-COVID-19) and infectious complications (12 out of 62 COVID-positive vs. 24 out of 191 COVID-negative patients). We conducted univariable and multivariable logistic regression analyses separately to identify independent risk factors for acute renal injury in patients with COVID-19. The univariate analyses showed that only ECMO flow (OR, 2.45; 95% CI, 1.53–3.94; $p=0.001$) was a significant risk factor for acute renal injury. Multivariate analyses showed that masculine gender (OR, 3.7; 95% CI, (1.64–8.34); $p=0.002$), body mass index (OR, 1.16; 95% CI, (1.08–1.24); $p=<0.001$), days on ECMO (OR, 1.08; 95% CI, (1.04–1.12); $p=<0.001$), sodium pre-canulation (OR, 1.09; 95% CI, (1.03–1.16); $p=0.003$), PaCO2 pre-canulation (OR, 1.03; 95% CI, (1.01–1.04); $p=0.001$), PaO2 pre-canulation (OR, 0.97; 95% CI, (0.96–0.99); $p=0.021$), HCO3 pre-canulation (OR, 1.29; 95% CI, (1.18–1.4); $p=<0.001$), Lactate pre-canulation (OR, 0.67; 95% CI, (0.64–0.83); $p=<0.001$), base excess pre-canulation (OR, 1.16; 95% CI, (1.10–1.23); $p=<0.001$), APACHE II score (OR, 0.94; 95% CI, (0.9–0.99); $p=0.035$), DEOx (OR, 0.94; 95% CI, (0.92–0.96); $p=0.001$), red blood transfusion (OR, 10.94; 95% CI, (2.5–47.89); $p=0.001$), use of heparin (OR, 4.99; 95% CI, (1.94–12.62); $p=0.001$), ECMO Flow (OR, 3.17; 95% CI, (2.15-4.68); $p=<0.001$), respiratory frequence pre-canulation (OR, 1.14; 95% CI, (1.06–1.23; $p=<0.001$), PEEP pre-canulation (OR, 1.45; 95% CI, (1.27–1.67); $p=<0.001$), FiO2 pre-canulation (OR, 1.03; 95% CI, (1.01–1.04); $p=<0.001$), plateau pressure pre-canulation (OR, 1.10; 95% CI, (1.04–1.15); $p=<0.001$), Glomerular filtration (OR, 1.01; 95% CI, (1.01–1.02); $p=<0.001$) were significant risk factor for acute kidney injury after adjusting all variables. We evaluated model discrimination using the area under the receiver-operating characteristic (AUROC) curve which was 0.79 for base excess pre-canulation, 0.716 for BMI, 0.616 for red blood transfusion, 0.815 for ECMO flow, 0.620 for masculine gender, 0.617 for sodium pre-canulation and 0.624 for heparin infusion.
**Conclusions:** This study highlights significant differences in risk factors and the progression of AKI among patients undergoing ECMO therapy with and without COVID-19 such as male gender, higher base excess pre-canulation, higher BMI, red blood transfusion, ECMO flow, sodium pre-canulation and heparin infusion. These findings emphasize the importance of tailored management approaches for patients requiring ECMO, which could improve clinical outcomes and reduce the incidence of complications, including AKI.

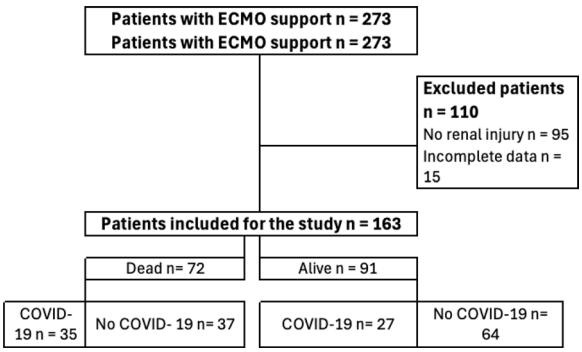

**Fig. 1 (abstract 001603)** Flowchart of subject enrolment in the study

**Table 1 (abstract 001603)** Characteristics of the patients.

| Characteristics | Population n = 163 | COVID-19 = 62 | No COVID-19 = 101 | p-value |
|---|---|---|---|---|
| Age in years, mean (SD) | 43.9 (12.5) | 42.1 (9.6) | 44.1 (14.1) | 0.279 |

**Introduction:** Pulmonary complications (PC) and pressure injuries (PI) are frequent occurrences in critically ill patients, with supine positioning and prolonged immobilization being the main risk factors. Repositioning is a strategy to mitigate the effects of immobility on the development of pressure injuries and pulmonary complications. Automatic, constant, and programmable flow change, known as continuous lateral rotation therapy (CLRT), through special beds, in its longitudinal axis, can be an alternative for treating critical patients. Therefore, we investigated the effectiveness of new therapies, such as CLRT, that prevent these events, providing a greater understanding of the use of these technologies in clinical practice.
**Objectives:** The objective of this systematic review was to investigate the effectiveness of continuous lateral rotation therapy (CLRT), compared to manual lateralization, in preventing pressure injuries and pulmonary complications in critically ill patients.
**Methods:** Our systematic review was registered with PROSPERO (CRD42022385309), guided by PRISMA guidelines. Clinical trials evaluated were included from inception until January 15, 2023. We considered studies that used CLRT for the prevention and treatment of pulmonary complications and pressure injuries, regardless of the population (clinical and surgical). For critical evaluation, description, and synthesis of the data, we followed the JBI recommendations. We used JBI SUMARI to analyze the methodological rigor of the included studies. Homogeneous studies were grouped into statistical meta-analysis using JBI Sumari. Heterogeneity was assessed statistically using standard chi-square and I-square tests.
**Results:** From a total of 3913 relevant studies, 11 studies were included, with 887 participants meeting the inclusion criteria. No study met all validity criteria of the methodological assessment. We identified that CLRT is used for the treatment and prevention of respiratory complications, with records dating back to 1988; however, there is still a gap regarding its effect on the skin of critically ill patients. We found that CLRT has no impact on mortality (RR 0.86, 95% CI [0.64–1.15], $p = 0.31$) and mechanical ventilation (MV) time (MD − 1.24, 95% CI [− 3.17–0.70], $p = 0.21$). However, CLRT reduced the incidence of Ventilator-Associated Pneumonia (VAP) (RR 0.47, 95% CI [0.31–0.69], $p < 0.001$).
**Conclusions:** Continuous Lateral Rotation Therapy did not achieve statistical significance in association with a reduction in mechanical ventilation time and overall patient mortality, but it is effective in reducing the incidence of adverse events associated with MV, especially VAP. The effectiveness of CLRT on the skin remains difficult to assess. It is recommended to carry out an appropriately planned RCT, determining whether the apparent benefits of this therapy are worth the risks and costs.

**Introduction:** Monitoring intracranial pressure (ICP) is crucial in the choice of the best management for severe traumatic brain injury (TBI) since it is associated with high mortality and poor clinical outcomes when elevated. Nevertheless, the invasive aspect of this method carries complication risks such as bleeding and infection. Transcranial Doppler monitoring in the Intensive Care Unit (ICU) is a non-invasive method that can predict the increase of ICP through the detection of reduction of cerebral perfusion. Therefore, information about pathologic hemodynamic changes can be quite impactful on therapeutic considerations and the evaluation of the severity of the injury.
**Objectives:** To evaluate the impact of TCD monitoring on the management of TBI through controlled studies.
**Methods:** A systematic review was performed using the following combinations of MESH terms and Boolean operators: 'transcranial doppler ultrasonography' AND 'traumatic brain injury' AND 'management' on the bases MEDLINE via PubMed, EMBASE and SCOPUS from inception to April 2024. Only controlled studies were selected and the exclusion factors were theme fugue, repeated articles, and noncontrolled studies. The review was carried out under the methodological recommendations of the PRISMA guideline. We collected data on outcomes, the influence of TCD on early intervention, and prediction of prognosis and ICP elevation.
**Results:** Seven out of 34 articles were selected. Four of them concluded that TCD monitoring had a significant positive impact on early intervention, such as initiating ICP monitoring or operating a decompressive craniectomy, due to correct prediction of high ICP, the occurrence of post-traumatic vasospasm and hyperemia, and prevention of secondary ischemic injuries. Three of the selected studies found a correlation between TCD monitoring and favorable outcomes, improvement of long-term prognosis of patients that suffered from TBI, and prediction of TBI management outcomes. In addition, one study found that TCD can be useful in ruling out intracranial hypertension in situations where invasive methods cannot be used or are unavailable.
**Conclusions:** TCD monitoring of patients who suffered TBI in the ICU enables more secure early intervention, allows the prediction of patient prognosis, and is associated with favorable outcomes. Also, it can be useful in avoiding secondary cerebral injury through early detection of pathologic hemodynamic changes. Therefore, we found that TCD monitoring is a powerful non-invasive tool with a highly positive impact on effectively changing the usual course of severe brain damage after TBI.

**Introduction:** Ketogenic enteral nutrition (KEN) with minimal carbohydrate content is known to improve the quality of [18F]-desoxyglucose positron emission tomography ( [18F]-FDG PET), as it reduces background uptake of glucose and [18F]-FDG [1]. In our institution, if a cardiac focus is part of the differential diagnosis, we strive to start KEN 48 h before the planned PET-scan. The time required to achieve lower and stable glucose levels as well as minimal insulin requirements, is not known.
**Objectives:** To study the time course of glucose control and insulin resistance in critically ill patients in whom KEN was initiated.
**Methods:** We examined glucose levels and insulin requirements from 120 h before till 48 h after the initiation of ketogenic feeding in adult patients treated in our ICU. This feeding consisted of KetoCal 4:1 enteral feeding (Nutrison) with 1 kCal/ml. The administration rate of KetoCal was adjusted to the previous caloric intake with standard enteral nutrition. Glucose levels were controlled by a nurse-centered computer program (GRIP), that was blinded for the type of feeding. Daily glucose levels and insulin requirements in IU/h were recorded. Daily glucose variability was also determined. Ketone levels were measured directly before the [18F]-FDG PET scan. Means were compared with the Student's *t*-test.
**Results:** We examined 9 sequential patients (5 males), aged $58 \pm 10$ years, who received KetoCal 4:1 at rates varying from 20 to 60 ml/h. In 8 patients it was given for FDG-PET preparation and in one patient as the treatment for super-refractory status epilepticus. During the study period, 565 glucoses were measured, resulting in 230 insulin adjustments by the GRIP system.
Glucose levels, glucose variability, insulin requirements and IR showed a marked decrease after initiation of KEN. From the period of 24h to 0h before starting KEN to 24h to 48h after starting KEN, the mean ($\pm$ SD) glucose changed from $7.6 \pm 0.7$ to $6.0 \pm 1.6$ mmol/L ($P = 0.01$) and glucose variability decreased from $1.5 \pm 0.8$ to $0.5 \pm 0.2$ mmol/L ($P = 0.004$).
Insulin requirements dropped $1.1 \pm 11$ to $0.2 \pm 0.3$ IU/h ($P = 0.02$). Two days after KEN, ketone levels were $1.7 \pm 2.2$ mmol/L.
**Conclusions:** Within two days after initiation of KEN, glucose levels, glucose variability and insulin resistance displayed a remarkable decrease. Whether these measures serve as a surrogate marker for optimal [18F]FDG-PET image quality in ICU patients, similar to ketone levels [1], needs further investigation.

## Evaluating anesthesiologists' awareness about sevoflurane impact on climate change

G. Scandurra[1], P. Dony[1]
[1]Service d'anesthésie, Civil Hospital Marie Curie, Charleroi, Belgium
**Correspondence:** G. Scandurra
***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001607

**Introduction:** Climate change is one of the imperative problems we need to face in the current century.
Greenhouses gases (GHGs) emissions are completely destabilizing our planet's weather and climate system by increasing average temperature, causing extremes weather events, changing wildlife habitats, rising seas surface and declining air quality with a negative impact on human health.
Volatile anesthetics are recognized to contribute to climate change by altering the photophysical properties of the atmosphere 1,2,3. Sevoflurane particularly does not catalytically destroy ozone but its trace in the earth's atmosphere absorbs and reduces outgoing infrared thermal energy warming the environment. Determining the exact climate impact of worldwide anesthetic procedures using sevoflurane is complicated because of limited available data on the usage of anesthetic agents, that's why we are studying them. Although the contribution of volatile anesthetics to total GHG emissions is small (0.1%) compared with CO2 (82.2%), it is still important to consider the long-term, cumulative impact of inhaled anesthetics on climate change, finding strategies to minimize the introduction of these agents into the environment.2,3,4
**Objectives:** 1. Understanding anesthesiologists' awareness and attitude about sevoflurane impact on climate change. 2. Analyzing the average consumption of sevoflurane at « Marie Curie» Hospital in Charleroi
**Methods:** We used an anonymous survey based on an ad hoc questionnaire conducted in March and planned to last until April 2024, to investigate anesthesiologists' perception of sevoflurane gas consumption and its impact on climate change. We observed the relationship between their knowledge and a pro-environmental action at their workstation. The population of our study will be represented by 200 certified anesthesiologists and anesthesia residents, living in Belgium, Italy and France.
We performed a retrospective registry-based cohort study between January 2015 and July 2023 in Marie Curie Hospital, using anesthesia information management systems and the departmental hospital databases. The link between the handwritten data from the pharmacy represents the quantity estimated by the anesthesiologist of gas consumed during the act of anesthesia. The amount used is obtained from the information provided by the ventilator at the end of each procedure. The possible savings are based on the scientific recommendations to be applied to the settings of the anesthesia respirators. The comparison of these data constitutes the basis of the analysis.
**Results:** Preliminary findings are based on 130 anesthesiologists' replies. Our results show that 45.38% of our anesthesia providers never read about the impact of anesthesia on global warming; 53.85% have read articles about this subject but only 88.24% of them were convinced that inhaled anesthetics contribute to global warming. 87.88% are ready to receive ecological information adapted to their profession as anesthesiologist and 89.8% would like to adopt strategies to reduce the consumption of sevoflurane in their professional habits.
Other results are under analysis.
**Conclusions:** This study highlights the fact that there are still too many anesthesiologists who are unaware of anesthetic gases impact on climate, but most of them are ready to incorporate environmentally conscious anesthetics practices to reduce global pollution. It is imperative to raise awareness of volatile anesthetics consumption and promote volatile gas-sparing strategies to combat climate change.

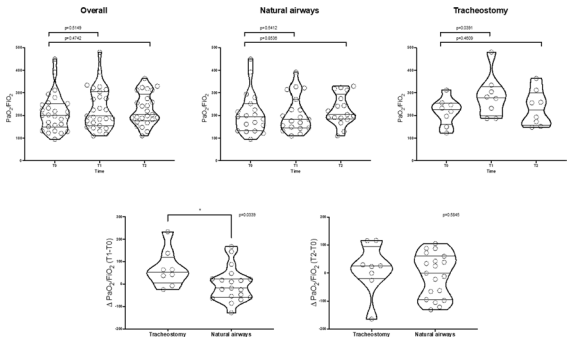
**Introduction:** Ez Positive Airway Pressure (EzPAP), a non-invasive positive airway pressure system, prevents and treats atelectasis while promoting lung expansion [1–3].
**Objectives:** The primary aim was to assess the early effect of EzPAP on gas exchange in critically ill subjects who were spontaneously breathing after a period of invasive mechanical ventilation. Secondary aims included evaluating the early effects of EzPAP on hemodynamics and the Respiratory Distress Observation Scale (RDOS, dyspnea scale). Changes in the Radiological Atelectasis Score (RAS) before and after 1-week treatment (1–2 sessions/day) were also evaluated. Outcomes were compared between subjects utilizing EzPAP via natural airway and tracheostomy.
**Methods:** An observational pre-post study was conducted at a University hospital. Spontaneously breathing adult subjects admitted to the intensive care unit, with chest X-ray suggesting the need for lung re-expansion after a period of invasive mechanical ventilation, were inclusion criteria. Exclusion criteria were life-threatening conditions, intracranial hypertension, hemodynamic instability, and pneumothorax. Data about gas exchange, hemodynamic, and RODS were collected at T0 (before EzPAP), T1 (immediately after EzPAP), and T2 (2 h after EzPAP).
**Results:** The subjects included in the study were 27 ($n=19$ with natural airways and $n=8$ with tracheostomy) out of a total of 213 eligible patients. The median age was 65 (IQR = 58–74) years, and 66.7% were male (Table 1). In the overall population and subjects with natural airways, arterial partial pressure of oxygen to fraction of inspired oxygen (PaO2/FiO2) did not differ between T1 and T0 ($p=0.52$ and $p=0.54$) and T2 and T0 ($p=0.47$ and $p=0.85$). Considering the subjects with a tracheostomy, PaO2/FiO2 was higher at T1 (median [IQR] = 279 [199–327] mmHg) than at T0 (226 [162–254] mmHg, $p=0.039$). The same improvement was not achieved at T2 compared to T0 (Fig. 1). Arterial partial pressure of carbon dioxide (PaCO2) did not change in the overall cohort, nor between natural airways and tracheostomy. Hemodynamics did not change over time in the overall population and in natural airway vs. tracheostomy. In the overall population and in subjects with natural airways, the respiratory rate was lower at T1 vs. T0 ($p=0.010$ and $p=0.027$). Symptoms of dyspnea did not improve by the application of EzPAP therapy. RAS improved within about one week of treatment in the overall population (T1 median [IQR] 2 [1.25–3] vs. T0: median [IQR] 3 [2–3.75], $p<0.0001$).
**Conclusions:** In critically ill spontaneously breathing subjects, EzPAP did not improve gas exchange, despite ameliorated RAS after about 1-week. The use of EzPAP was safe regardless of hemodynamic stability. EzPAP therapy showed no improvement in dyspnea symptoms.



**(abstract 001611)** Effect of EzPAP on $PaO_2/FiO_2$ ratio in all patient, natural airways and tracheostomy. Dots represent individual patients. The violin plots represent delta changes (between two-time points) in PaO2/FiO2 (T0, baseline; T1 immediately after EzPAP; and T2, 2-h after EzPAP). Dots represent individual patients. ***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001612

**Introduction:** Vasopressin (AVP) has been proposed as a secondary vasopressor therapy for patients with septic shock who are already receiving norepinephrine (NE) and with persistent arterial hypotension instead of increasing NE dosage. Nevertheless, the threshold for adding AVP remains unclear.1
Therefore, the place of AVP in the management of patients with vasodilatory shock is still debated with significant heterogeneity between Intensive Care Units (ICUs), as the optimal timing, dosage, duration, and modalities of vasopressin weaning remain subjects of clinical debate. 2
**Objectives:** The aim of this study is to get an up-to-date picture of the AVP use in patients with vasodilatory shock in a tertiary center.

**Methods:** Single tertiary center, retrospective cohort study of adult patients receiving AVP between April 1, 2020, and December 31, 2022. The primary outcome is in-hospital mortality.
**Results:** Seventy-one patients (mean age 60 ± 15 years, male 63.4%) received AVP.
The mean Acute Physiology and Chronic Health Evaluation (APACHE) II score was 29.1 ± 7.9 and the mean Sequential Organ Failure Assessment (SOFA) score was 11.9 ± 3.3.
All patients underwent invasive mechanical ventilation, with 57.7% requiring renal-replacement therapy and 8.5% being supported by extracorporeal membrane oxygenation (ECMO).
NE was administered to all patients, with a median dose of 1.3 ± 0.5 µg/kg/min. The mean time between initiation of NE and AVP administration was 10.9 ± 8.2 h. The maximum dose of AVP was 0.04 IU/min.
AVP effectively increased mean arterial pressure (MAP) and reduced NE requirements across the patient cohort, with 57.8% of patients demonstrating a pressure response. This response correlated with lower catecholamine doses, reduced mortality rates and shorter lengths of hospital stay.
Ischemic complications occurred in 7 patients, including digital ischemia (4.2%), acute mesenteric ischemia (2.8%), stroke (1.4%) and acute myocardial ischemia (1.4%). The incidence of ischemic complications was associated with higher NE doses (1.6 µg/kg/min) and prolonged exposure to elevated AVP doses (0.03–0.04 IU/min).
In-hospital mortality rate was 50.7% ($n = 36$), primarily due to multi-organ failure. Deceased patients had a higher median age (64 ± 11 y), higher NE doses (1.5 ± 0.5 µg/kg/min, $p$-value 0.5), delayed AVP initiation (12.4 ± 8.4 h, $p$-value 0.07) and a lesser decrease in MAP (17% vs 41%).
**Conclusions:** A favorable hemodynamic response to AVP therapy was associated with improved mortality outcomes, suggesting that hemodynamic response may be an appropriate marker of the efficacy of AVP. Consistent with existing literature, patients with lower baseline NE doses and early initiation of AVP appear to benefit more from AVP.
Furthermore, AVP administration was associated with a low incidence of ischemic events, supporting its safety profile in this patient population.

### Mechanical Insufflation:Exsufflation is effective and safe in patients undergoing active ICP management in a Neurosciences Critical Care Unit

S. Petty[1], A. Wood[1]
[1]NCCU, Addenbrooke's Hospital, Cambridge, United Kingdom
**Correspondence:** S. Petty
***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001614

**Introduction:** Acute brain injury (ABI) is associated with impaired sputum clearance, aspiration pneumonia and ventilator-associated pneumonia. Commonly, these patients require careful management of PaCO2 to prevent cerebral ischaemia and control intracranial pressure (ICP), alongside adequate oxygenation and are often sedated and given neuromuscular blockade to achieve control. Peak cough flow of above 160 l/min is required for an effective cough and less than 270 l/min is associated with increased secretion retention. Bronchoscopy is widely used for secretion clearance but can induce a significant rise in ICP, even with adequate sedation. The other limitation is the size of the bronchoscope used as this will determine the subsegmental bronchial level that can be reached. Mechanical insufflation:exsufflation (MI:E) is a device used when a cough is absent/ineffective. Whilst commonplace in some pathologies e.g. high spinal cord injury it is much less common in patients who are undergoing active ICP management.
**Objectives:** To determine whether MI:E is feasible and safe to use for sputum clearance in ventilated ABI patients on ICP protocol.
To determine whether MI:E will lead to reduction in pressure required to generate required tidal volume.
To determine whether ETCO2, cerebral perfusion pressure (CPP) and ICP can be maintained at safe values during MI:E treatment.
To determine frequency and type of adverse effects.
**Methods:** Ventilator data was used to determine starting insufflation pressures, titrating up as required. Oxygen was supplemented through the circuit. Variable ratio MI:E was used in a manual mode, alongside positioning, to clear sputum load with endotracheal tube suction. Changes to peak pressures (Ppk) that were sustained for longer than one hour were recorded. Changes to FiO2 that were sustained were also recorded. ETCO2, ICP and CPP were continuously monitored. Adverse events were recorded and intervention provided.
**Results:** Fourteen patients underwent one or more episodes of MI:E. 30 out of 32 episodes of MI:E resulted in reduced pressure to generate prescribed tidal volume, indicating improved pulmonary compliance (Fig. 1). The largest drop in plateau pressure (Pplat) was from 30 to 23.
Two patients required sedation bolus and one required titration of noradrenaline. One patient obstructed their proximal bronchi during treatment, requiring manual ventilation and saline instillation to clear. ICP and CPP were stable in all patients. ETCO2 was well-controlled during MI:E, in keeping with ESICM consensus. A further 8 patients on pressure support ventilation demonstrated a decreasing trend in FiO2 requirements following treatment with MI:E.
**Conclusions:** MI:E can be used safely and to good effect in acute brain-injured patients undergoing active ICP management, at all stages of ICP Prorocol (1–4).
We found a near-universal improvement in lung compliance following MI:E therapy with no adverse effects on ETCO2 clearance, ICP, CPP and minimal adverse cardiovascular effects.
MI:E can be used to good effect in brain-injured patients on ICP protocol with ICP remaining stable, CPP targets achieved and with minimal cardiovascular instability.
Although not tested in a head-to-head manner, our impression was that MI:E was more beneficial for sputum clearance than bronchoscopy in a small number of patients.
In this small study, this approach appears safe and effective, further studies are required to definitively establish safety and superiority to other techniques such as bronchoscopy.

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001616

**Introduction:** Healthcare is characterized by constant change and innovation to keep pace with technological advancements, regulations and scientific insights, aiming to elevate patient care standards. This makes continuous change inevitable. However, frequent and continuous exposure to poorly managed changes can lead to change fatigue among healthcare workers. Change fatigue is defined as feelings of stress, exhaustion and apathy caused by rapid and continuous change. Consequences of change fatigue are disengagement, increased rates of absenteeism, resistance, burnout and change failure. To pursue change success, improve patient care and safeguard employees wellbeing, it is crucial to know the factors contributing to the development of change fatigue and ways to mitigate change fatigue.
**Objectives:** To integrate empirical and theoretical literature on factors facilitating change fatigue and barriers to mitigate change fatigue in healthcare professionals.
**Methods:** An integrative review following the six-step Whittmore and Knafl methodology was conducted. A search was conducted in the PubMed, Embase, Cochrane and CINAHL databases. Quality was assessed using the Mixed Methods Appraisal Tool (MMAT) quality assessment tool.
**Results:** Twenty-six articles were included in this review, including 22 empirical studies and 4 theoretical articles. From these articles, groups were identified on 1) facilitating factors for change fatigue and 2) factors that act as barriers and mitigate change fatigue.
**Conclusions:** Healthcare workers are constantly subjected to change, and therefore are at risk of developing change fatigue which has major consequences. The outcomes of this review provide an overview of organizational and individual factors acting as facilitators and barriers to the development of change fatigue, presented in Fig. 1. Organizational factors include frequent and continuous change, higher workload, unpreparedness, low organizational commitment and weak planning. Individual factors include high (psychological) demand, negative feelings of powerlessness and uncertainty. Factors that act as barriers and help to mitigate change fatigue on the organizational level are adaptive reserve, engagement and empowerment of staff, providence of education and information, reduction of workload and adequate management and leadership skills regarding change communication and planning. On the individual level, resilience, defined as the ability to successfully adapt to stressors, maintaining psychological well-being in the face of adversity, acts as the most important barrier to change fatigue, alongside job satisfaction and commitment to change. Factors that enhance resilience include mindfulness, qualification, education and job satisfaction. These findings should be considered to improve future changes, mitigate change fatigue and enhance change outcomes.

*Intensive Care Medicine Experimental* 2024, **12 (suppl 1)**: 001617

**Introduction:** Transfusion-associated circulatory overload (TACO) is a major transfusion complication, accounting for 23% of all transfusion-related fatalities. Understanding of potential risk factors remains limited. Previous pre-clinical studies explored the impact of plasma and red blood cell transfusion in TACO. However, platelet transfusions, among all blood products, result in the highest overall number of adverse reactions per unit transfused and its effects on TACO remain unexplored.
**Objectives:** Our aim is to determine if platelet transfusion induces circulatory overload more than crystalloids and evaluate if it leads to a more severe phenotype than plasma transfusion in a rat heart failure model, with the overarching goal of shedding light on the pathophysiology of TACO.
**Methods:** We utilized a validated TACO model in male anaemic Wistar rats with acute myocardial infarction. Animals were randomized into three groups: platelets ($n=11$), plasma ($n=10$), or Ringer's lactate ($n=11$). The primary outcome was the difference between pre- and post-transfusion left ventricular end-diastolic pressure (ΔLVEDP) measured with a left ventricular catheter. Secondary outcomes included pulmonary wet/dry weight ratio, circulating biomarkers, and arterial blood gas measurements. Data are expressed as mean and standard deviation.
**Results:** Pre-transfusion characteristics, including cardiac infarct size, LVEDP and P/F ratio were comparable between groups. The ΔLVEDP following platelet transfusion (10.4 mmHg ± 4.6) was significantly larger than the ΔLVEDP following Ringer's lactate infusion (0.9 mmHg ± 1.4), $p<0.001$. ΔLVEDP following plasma transfusion (13.0 mmHg ± 7.7) did not significantly differ from ΔLVEDP following platelet transfusion ($p>0.5$). Pulmonary wet/dry weight ratio did not differ among groups ($p>0.5$), however, when compared to control animals all groups had a significantly larger wet/dry weight ratio ($p<0.05$). Biomarker of heart failure (NTpro-BNP) did not differ between groups at termination ($p>0.1$), there was a significant increase in NTpro-BNP from baseline (50 pg/ml ± 24) to termination (177 pg/ml ± 86) across all groups ($p<0.001$). At termination, the P/F-ratio was significantly lower after platelet transfusion (599 ± 77) compared to Ringer's Lactate (721 ± 128; $p<0.05$), whereas no significant difference was observed after plasma transfusion (675 ± 83; $p>0.1$).
**Conclusions:** Platelet transfusion induces circulatory overload, as evidenced by an increase in LVEDP, comparable to that induced by plasma transfusion in rats with myocardial infarction when compared to Ringer's lactate. However, lower P/F-ratio's suggest that platelet transfusion may lead to greater pulmonary injury. Further investigation is warranted to elucidate whether similar underlying pathophysiological mechanisms are involved.

*Intensive Care Medicine Experimental* 2024, **12 (suppl 1)**: 001618

**Introduction:** Tissue red blood cell perfusion (tRBCp), which integrates capillary density and blood flow, has been proposed as a novel target for fluid resuscitation. Despite systemic hemodynamic responses or lack thereof to fluid responsiveness tests, microcirculation may exhibit a different response, highlighting the dissociation between macrocirculation and microcirculation. This study examines the tRBCp responses in critically ill patients during fluid responsiveness tests.
**Methods:** CI was measured using pulse contour analysis (PiCCO2 and PulsioFlex) during passive leg raising (PLR), PEEP test (decrease in positive end-expiratory pressure by 5 cmH2O in mechanically ventilated patients), and fluid challenge (500 mL normal saline I.V. in 15') in critically ill patients with acute circulatory failure. Preload responsiveness was defined as an increase in CI ≥ 10% during the PLR test, ≥ 9% during the PEEP test and ≥ 15% during volume expansion.

Microcirculation was assessed with Cytocam at baseline and during fluid responsiveness tests. The three best quality videos according to the Massey Score were selected for each time-point and analyzed using MicroTool automatic software.
**Results:** Thirty-three measurements were taken including 21 in septic shock patients, 6 in cardiogenic shock and 5 in hypovolemic shock (age: 77 [44–78], SOFA score: 9 [7–11], SAPS II:47 [39–58], lactate: 1.8 [1.2–2.5] mmol/l). One patient was excluded because missing microcirculation measurement during fluid responsiveness measurement.
tRBCp changes after test correlated negatively with the baseline tRBCp (ΔtRBCp: $R = -0.53$, $p < 0.002$, Fig. 1). Patients with higher initial tRBCp were more likely to experience a deterioration of microcirculation after fluid responsiveness test. On the contrary, an impaired microcirculation at the baseline were more likely to improve after the test. Notably, responders to fluid responsiveness tests showed a significant lower pre-test red blood cell velocity (RBCv) in comparison to non-responders (mean: 354.2 µm/s [SD: 32.8] vs 387.2 µm/s [SD: 30.8], Fig. 2). The RBCv were not different among responders and not-responders after the test (376.3 µm/s [45.1] vs 390.0 µm/s (56.4), Fig. 2).
**Conclusions:** This study confirms the dissociation between macro- and microcirculatory responses during fluid responsiveness tests. It reveals that patients with higher initial tRBCp typically experience worsened microcirculation post-test, whereas those with impaired baseline microcirculation often improve. Notably, fluid responsiveness appears more related to changes in blood flow rather than capillary recruitment. These findings suggest that baseline microcirculation should be considered in fluid resuscitation strategies, highlighting tRBCp's potential as a critical marker for tailored fluid therapy.

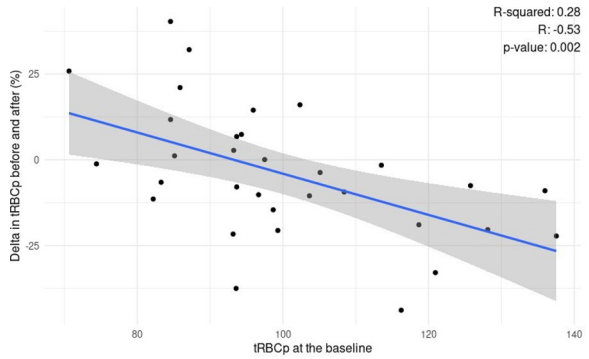

**Fig. 1 (abstract 001618)** Changes in tissue Red Blood Cell perfusion (tRBCp) after fluid responsiveness test in correlation with the pre-test baseline tRBCp

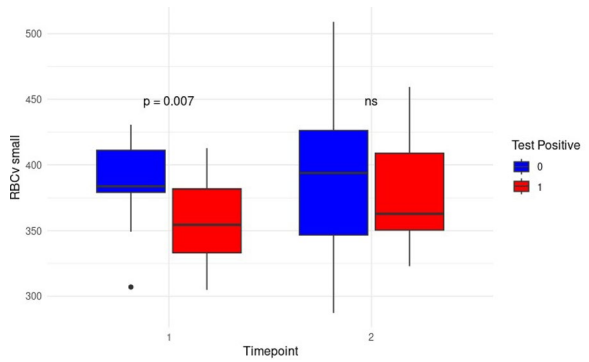

**Fig. 2 (abstract 001618)** Comparison of the capillary Red Blood Cell velocity (RBCv) among responders and non-responders before and after the fluid responsiveness test

### What happens after ECMO?—follow-up of patients needing extracorporeal membrane oxygenation

M.P. Vidal[1], A. Santos[1], I. Santos[1], G.C. Almeida[1], S. Beirão[1], E. Sousa[1]
[1]Intensive Care Unit, Unidade Local de Saúde de Coimbra-Hospitais da Universidade, Coimbra, Portugal
**Correspondence:** M.P. Vidal
***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001619

**Introduction:** Critical illness has an impact on long-term health status and quality of life. Adults who recover from ICU can develop muscle weakness, cognitive impairment, difficulties in managing activities of daily living and returning to work, and psychological problems such as depression/anxiety.
ECMO is an increasingly common supportive therapy. Sedation and immobility are necessary in most patients, resulting in high rates of delirium and physical impairment. Therefore, patients requiring ECMO are at high risk of post intensive care syndrome (PICS).
**Objectives:** Analyze survivor outcomes, patient-reported outcome measures and identify PICS at follow-up evaluation.
**Methods:** Evaluation of patients that underwent ECMO after ICU discharge since July 2021. Evaluation occurred 6 months–1 year post discharge. Surveys were applied to assess patients' current health status, identify PICS related symptoms such as pain, anxiety/depression, mobility, and difficulties managing personal care and daily activities.
**Results:** From July 2020 to June 2023, 69 patients underwent ECMO. ICU mortality was 39.1%. Of the 42 surviving patients, 2 passed away at home before the follow-up. In 6 patients, follow-up was lost. 3 patients did not attend the follow-up appointment. In 2 patients follow-up process was not initiated at the time data was collected.
29 patients were evaluated at the outpatient follow-up appointment. 27 (93.1%) underwent ECMO due to ventilatory failure (26 due to ARDS; 1 due to massive hemoptysis), and 2 (6.9%) due to circulatory failure. Delirium was reported in 18 of the patients (62.1%).
Regarding previous health condition, 20.7% considered themselves completely healthy, while 79.3% reported non-disabling chronic conditions.
At follow-up, 2 patients (6.9%) reported persistence of extreme pain, while 9 (31.0%) reported moderate pain.
10 Patients (34.5%) reported anxiety/depression symptoms after ICU discharge—9 with moderate symptoms, while 1 reported extreme anxiety/depression, severely impacting daily life.
Most patients could manage their personal care (82.8%), and 58.62% of patients returned to their daily life activities. Only 1 patient was uncapable of managing personal care, and 2 were unable to return to their activities.
Concerning self-reported current state of health, patients ranked themselves on a scale from 0 to 100, based on previous health condition. 16 ranked themselves 81 or higher; 7 from 61 to 80; and 4 from 41 to 60.
More than 90% of patients maintain hospital follow-up, and more than 2/3 are still in active rehabilitation.
**Conclusions:** Functional outcome is mostly good in surviving patients previously submitted to ECMO, with the majority returning to their daily activities in less than a year.
PICS is a complex condition that overlaps with many other disorders, making its prevention, identification, and treatment during and after ICU stay paramount.
More in-depth work is needed to truly evaluate the impact of ECMO on long-term patient quality of life.

**Correspondence:** R. Antolini
***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001620

**Introduction:** Patients admitted to intensive care units who are fluid responders require fluid administration to increase cardiac index (CI) and then tissue perfusion. Currently, several tests exist to predict whether a patient can increase CI following fluid administration, but the behavior of the microcirculation in these circumstances and after volume expansion remains unclear. The aim of this study is to analyze changes in the microcirculation during fluid responsiveness tests and after volume expansion.
**Methods:** CI was measured using pulse contour analysis (PiCCO2 and PulsioFlex) during passive leg raising (PLR), PEEP test, and fluid challenge (500 mL normal saline in 15') in critically ill patients with acute circulatory failure. Preload responsiveness was defined as an increase in CI $\geq$ 10% during the PLR test, $\geq$ 9% during the PEEP test and $\geq$ 15% during volume expansion.
Microcirculation was assessed with Cytocam at baseline, during fluid responsiveness tests, and after volume expansion to assess the proportion of perfused vessel (PPV), total vessel density (TVD) and functional capillary density (FCD). The three best-quality videos according to the Massey Score were selected for each time point and analyzed using MicroTool automatic software.
**Results:** Thirty-eight measurements were taken including 21 in septic shock patients, 6 in cardiogenic shock and 5 in hypovolemic shock (age: 77 [44–78], SOFA score: 9 [7–11], SAPS II:47 [39–58], lactate: 1.75 [1.2–2.5] mmol/l). Twenty-two measurements were made in patients treated with a median dose of norepinephrine of 0.320 [0.12–0.74] mcg/kg/min. Twenty-five PLR tests, 6 PEEP tests and 7 fluid challenges were performed. A total of 196 microcirculation videos were analyzed. PPV at baseline was 0.961 [0.933–0.977], TVD 26.095 [22.882–28.065] mm/mm$^2$ and FCD 24.588 [22.489–26.448] mm/mm$^2$. During the interventions, CI, mean arterial pressure (MAP) and MAP-CVP gradient increased, respectively, by 11.1 ($\pm$9.7)%, 6.5 ($\pm$8.2)%, and 5.7 ($\pm$8.5)% while the proportion of perfused vessels (PPV) decreased by 0.2 ($\pm$4.3)%. In preload non responder patients ($n=22$), PPV decrease by 1.5 ($\pm$4.8)% ($p=0.291$) and it increased by 1.6 ($\pm$2.8)% ($p=0.035$) in preload responders ($n=16$). This was the case in septic patients as in non-septic patients.
**Conclusions:** In critically ill patients with circulatory failure with a PPV at baseline $\geq$ 0.90, increasing cardiac output by increasing cardiac preload did not change PPV to a clinically significant extent, neither in preload responders nor in preload non-responders. The study is still ongoing.

### Commonly prescribed steroids for severe community-acquired pneumonia have differing immunosuppressive effects on monocytes and lymphocytes

M. Banerjee[1], K. Carthigesan[1], J. Ramanjula[1], T.A.C. Snow[1], M. Singer[1], N. Arulkumaran[1]
[1]Bloomsbury Institute of Intensive Care Medicine, University College London, London, United Kingdom
**Correspondence:** T.A.C. Snow
***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001621

**Introduction:** For patients with severe pneumonia, there are a few treatments available beyond antimicrobials to treat the infection and supportive care (oxygen, intubation etc.).
Steroids have been shown to have benefits in pneumonia, potentially by reducing inflammatory lung injury, however, they have numerous problematic side-effects including hyperglycaemia and immunosuppression leading to secondary infection [1–2].
'Steroids' encompass several classes and types of drugs with different effects. It is unclear which drug we should use, how much, for how long, and when it should be started. If we could demonstrate that certain steroids have a better immunosuppressive side-effect profile, that would help focus ongoing clinical research efforts.
**Objectives:** Identify whether there are differences in the immunosuppressive effects between corticosteroids used for management of pneumonia.
**Methods:** Healthy volunteer PBMCs were co-incubated for 24 h (monocytes, with heat-killed S *aureus*) or 72 h (lymphocytes, CD3/CD28 beads) with two concentrations of dexamethasone, hydrocortisone and methyl-prednisolone. Low and high doses were based on pharmacokinetic studies carried out in ICU patients [3].
Cells were analysed using flow cytometry to assess functions including:
Monocytes—Antigen presentation (HLA-DR, CD80, CD86), chemokine receptors (CCR2 and CXCR4), cytokine release (TNF-α, IL-1β, IL-6, IL-10), T-cell suppression (PD-L1), and glucocorticoid receptor expression.
Lymphocytes—Activation (CD28, CTLA-4), proliferation (IL-7R, IL-2R, % divided), cytokine release (IL-10, IFN-γ), cell death (viability, PD-1), and glucocorticoid receptor (GCR) expression.
Data expressed as a heat map of percentage change and analysed using Friedmans test, $p$-values < 0.05 denoted with a *.

**Results:** Dexamethasone altered monocyte antigen presentation (CD80 and CD86), chemokine receptor expression (CCR2) and cytokine release (IL-6). In lymphocytes dexamethasone reduced CTLA-4 expression, IL-7R expression, IFN-γ release and decreased cell viability.
Hydrocortisone caused upregulation of monocyte HLA-DR, altered chemokine receptor expression (CXCR4), and cytokine release (IL-6). It had no effect on lymphocyte function.
Methyl-prednisolone cased upregulation of monocyte HLA-DR but downregulation of co-stimulation (CD80 and CD86), altered chemokine receptor expression (CXCR4), and cytokine release (IL-1β and IL-6). In lymphocytes, it caused a decrease in viability.
All steroids suppressed GCR expression in monocytes, but only dexamethasone affected lymphocytes.
**Conclusions:** In volunteers, the immunomodulatory effect of steroids on monocyte and lymphocyte function is dependent on the type of steroid.
Dexamethasone seems to have multiple immunosuppressive effects above that of the other steroids.
Further work needs to explore whether this effect is seen in patients with pneumonia.

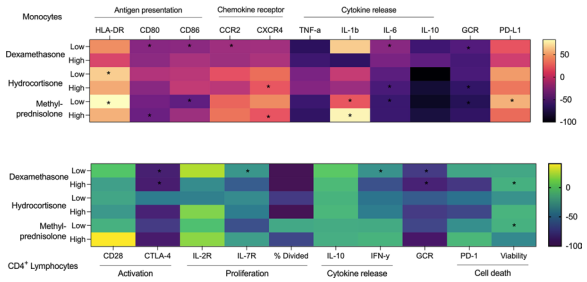

**Fig. (abstract 001621)** Percentage change of steroid compared to stimulated cells (monocytes—HKB, lymphocytes—beads). Significant values denoted by *

**Correspondence:** F. forfori
***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001622

**Introduction:** Sepsis-associated acute kidney injury (SA-AKI) is a complication that often can occur in critically ill patients causing high morbidity and mortality. Early diagnosis plays a key role in the prognosis of SA-AKI. Several studies have been conducted to assess whether there could be variables with predictive value toward SA-AKI. We carried out a single-center pilot study to determine whether clinical, laboratory and ultrasound parameters indicative of renal perfusion and venous congestion, could have predictive value and prognosis toward SA-AKI.
**Objectives:** The primary endpoint of the study is to correlate biological markers and ultrasonographic parameters with the development of AKI in patients with sepsis or septic shock, that may be useful in clinical practice to implement appropriate therapeutic measures. The secondary endpoint is to establish how the variation of these variables can be correlated with prognosis.
**Methods:** we prospectively enrolled critically ill patients with abdominal sepsis according to Sepsis-3 criteria. SA-AKI was defined combining Sepsis-3 and Kidney Disease Improving Global Outcomes (KDIGO) AKI criteria. We compared vital signs, sequential organ failure assessment (SOFA) score, Charlson Comorbidity Index, Simplified Acute Physiology Score (SAPS), procalcitonin (PCT), interleukin IL6 and IL10, serum Cystatin C levels, urinary Cystatin C levels, endotoxin activity between the sepsis-associated acute kidney injury (SA-AKI) group and sepsis without AKI group. Then, we evaluated intrarenal venous flow (IRVF), hepatic, portal and splenic vein patterns using Doppler ultrasonography, and venous excess ultrasound (VExUS) grading system prototype C. We measured inferior vena cava (IVC) diameter, renal doppler resistive index (RDRI), renal, splenic and hepatic venous impedance index (VII), portal vein pulsatility index. All these variables are collected at admission.
**Results:** 11 patients with abdominal septic shock were enrolled. Six patients developed SA-AKI within the first 72 h after admission to ICU. The median serum Cystatin C levels, SAPS III score, SOFA score were significantly ($p < 0.1$) higher in the SA-AKI group than in the sepsis without SA-AKI group on ICU day 1. The median RDRI was higher ($p$ 0.1126) in the SA-AKI group than in the sepsis without SA-AKI group on day 1. Multivariate logistic regression showed that the association of serum cystatin C, urinary cystatin C, IL6, and endotoxin activity on day 1 correlates with the presence of SA-AKI with AUC 0.9200 ($p < 0.05$). Also the combination of serum cystatin C, urinary cystatin C, IL10 on day 1 is associated with the development of SA-AKI with AUC 0.9200 ($p < 0.05$). Then, the association of serum cystatin C, renal VII, VExUS-C, RDRI is predictive of SA-AKI with AUC 0,9000 ($p < 0.05$). The venous congestion, detected by measuring renal, splenic and hepatic venous impedance index, IVC diameter and portal vein pulsatility index, correlates with the development of SA-AKI with AUC 0.9200 ($p < 0.05$). In addition, the results show that the association of SOFA score, Charlson Comorbidity Index and SAPS correlates with the presence of SA-AKI with AUC 0,8667 ($p < 0.05$).
**Conclusions:** In critically ill patients, the combination of biomarkers, such as serum and urinary cystatin C, interleukins and endotoxin activity, correlates with statistical significance with the development of SA-AKI. In addition, evaluation of ultrasonographic parameters may be useful to determining venous congestion and renal hypoperfusion, especially in association with laboratory biomarkers.

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001623

**Introduction:** It is poorly understood which physiologic parameters to monitor after a session of awake prone positioning in patients with acute hypoxemic respiratory failure. Identifying which early changes after prone positioning can help identify those patients with a lower risk of endotracheal intubation might help determine the appropriate monitoring tools to guide clinical decision-making, with the final aim of providing individualized treatments.
**Objectives:** We sought to assess which early physiologic changes after awake-prone positioning are associated with the receipt of invasive mechanical ventilation or death among patients with acute hypoxemic respiratory failure receiving high-flow nasal oxygen (HFNO).
**Methods:** We conducted a prospective cohort study of adult patients with COVID-19 related acute respiratory failure who received awake prone positioning. We assessed the association between relative changes in physiological variables (oxygenation, respiratory rate, pCO2 and respiratory oxygenation ratio [ROX] index) within the first 6 h of awake prone positioning and the risk of failure, defined as the composite of endotracheal intubation and/or death within 7 days. The relative change was computed as follows: value at time 1 (prone)—value at time 0 (supine) / value at time 0. A relative change in each physiologic parameter was calculated for each study patient and expressed as a proportion. For instance, a relative change in PaO2:FiO2 ratio of 25% would indicate an improvement in oxygenation of that magnitude. We used bivariate analysis to compare the baseline characteristics of patients with awake prone positioning failure and those with awake prone positioning success and fitted a multivariable logistic regression model to evaluate the association between patients' baseline characteristics (age, sex, disease severity [SOFA and APACHE scores] and baseline ROX index) and relative changes in the ROX index with the primary outcome of awake prone positioning failure.
**Results:** Between November 2020 and February 2022, 244 (70 female [29%], mean age 60 [SD 13] years old) patients were included. Seventy-one (29%) patients experienced awake prone positioning failure. Table 1 describes clinical and physiological features at baseline and relative changes within 6 h of prone positioning. Patients with awake prone positioning failure had lower mean [SD] ROX index at baseline (5.0 [1.4] versus 6.6 [2.2], $P < 0.0001$) and within 6 h of prone positioning (5.6 [1.7] versus 8.7 [2.8], $p < 0.0001$). After adjusting for baseline characteristics and severity scores, we observed that a relative increase of the ROX index compared to baseline (OR 0.37; 95% CI 0.25–0.54 every 25% increase) was associated with lower odds of failure (Fig. 1).
**Conclusions:** A relative increase in the ROX index within six hours of awake prone positioning is associated with a lower incidence of failure of awake prone positioning in patients with COVID-19 related acute hypoxemic respiratory failure. This may help select patients with most likelihood of benefiting from awake prone positioning.

**Table 1 (abstract 001623)** Clinical and physiological features at baseline and relative changes within 6 hours of prone positioning.

### Retrospective study comparing a number of presentations to the Emergency Department in the year preceding admission to ICU and mortality at one year post-ICU

M. Goel[1], L. Mei Lee[1], J. Dixon[1], M. Varrier[1]
[1]Intensive Care Unit St Helier Hospital, Epsom and St Helier University Hospitals, London, United Kingdom

*Intensive Care Medicine Experimental* 2024, **12 (suppl 1)**: 001625

**Introduction:** Patients are frequently referred to and admitted to the ICU during their last year of life. Identifying patients with a terminal trajectory is an important but challenging aspect of ICU decision-making. The number of emergency presentations in the past year is a simple, accessible, and objective metric. Multiple presentations are often viewed as a poor prognostic indicator. However, there is little published evidence to support this.
**Objectives:** This study looks to see if there is a correlation between the number of emergency attendances in the year prior to an ICU referral and mortality outcomes within 12 months of the referral date.
**Methods:** Retrospective notes were reviewed of those admitted to the ICU in a district general hospital over a three-month period (1st April 2022 to 30th June 2022). All ED presentations or non-elective admissions in the year before referral were tallied. Mortality outcomes were assessed based on survival status at 12 months post-referral.
**Results:** Records of 107 ICU-admitted patients during the study period were reviewed, with 40 patients deceased within 12 months (37.38% overall mortality). Mortality rates increased with higher emergency attendances, ranging from 29% for patients with no previous emergency or non-elective admissions to 67% for those with six attendances. However, mortality rates dipped for patients with four presentations (25%) and those with more than seven presentations (30%).
A 1-tailed Chi-square test revealed statistically significant differences in the risk of death between Group 1 (no/1 ED attendances) and Group 2 (2–6 attendances) ($p = 0.056$), as well as between Group 1 and the combined Group 2 and 3 ($p = 0.10$). However, no significant difference was observed between Group 1 and Group 3 ($p = 0.44$).
Odds ratios (OR) to evaluate the risk of death between Group 1 and Group 2, and between Group 1 and the combined Group 2 and 3, were 1.98 (95% CI: 0.85–4.64, $p = 0.11$) and 1.68 (95% CI: 0.76–3.71, $p = 0.20$), respectively.

| No. of ED attendances | Mortality (% of death over total) | Alive at 12 months | Dead at 12 months | Total |
|---|---|---|---|---|
| 0 | 29 | 15 | 6 | 21 |
| 1 | 34 | 27 | 14 | 41 |
| 2 | 50 | 6 | 6 | *12* |
| 3 | 60 | 4 | 6 | 10 |
| 4 | 25 | 6 | 2 | 8 |
| 5 | 50 | 1 | 1 | 2 |
| 6 | 67 | 1 | 2 | 3 |
| >7 | 30 | 7 | 3 | 10 |
| Total | | 67 | 40 | 107 |

**Conclusions:** The study suggests there may be an association between multiple emergency presentations (2 to 6 attendances) and increased risk of death compared to those with fewer presentations (< 2 times). However, further investigation with a larger sample size is needed for more accurate results. Interestingly, patients with more than six emergency presentations exhibited lower mortality rates, warranting further exploration into potential contributing factors such as resilience, demographic profile, or underlying mental health conditions among others.

### Proposing a scoring system for ARDS physiological subphenotyping: a supervised machine learning approach

G. Meza-Fuentes[1], M.A. Retamal[2], M. Barbé[1], I. Sánchez-Barraza[1], I. Delgado[3], R. López[4]

**Correspondence:** G. Meza-Fuentes
*Intensive Care Medicine Experimental* 2024, **12 (suppl 1)**: 001627

**Introduction:** Acute respiratory distress syndrome (ARDS) represents a significant burden on critical care, with a mortality rate of 45% and

accounting for 10.4% of global ICU admissions (1). Its clinical, radiological, pathological, and biological heterogeneity poses substantial challenges in patient management, including difficulties in treatment selection and patient stratification for clinical trials (2). The current ARDS definitions, though valuable, often fail to capture the diverse manifestations of the syndrome accurately. Hence, there is a pressing need for a simple yet effective method to subphenotype ARDS patients, allowing for personalized therapeutic strategies.

**Objectives:**

1. Develop a parsimonious supervised model to assign a score to ARDS patients based on physiological variables.
2. Evaluate the discriminative and predictive capacity of the proposed score for ARDS subphenotyping.

**Methods:** Leveraging previous research on ARDS physiological subphenotypes through clustering with a Gaussian mixture model, we developed a parsimonious supervised model using logistic regression. This model utilized the physiological subphenotypes identified in previous research as labels for classification. It allowed for the weighting of influential variables, based on their odds ratios, in discriminating subphenotypes. Subsequently, a final score, derived from these variables, demonstrated high discriminatory power and enabled patient stratification. Finally, a defined cut-off score was determined according to the Youden index of the ROC curve.

**Results:** The supervised model allowed a score to be assigned to each patient with ARDS to predict subphenotype 2, which is more severe, restrictive, and less ventilator-efficient than subphenotype 1 (Fig. 1). The variables that best-predicted subphenotype 2, aiming to capture its physiological severity, were respiratory rate (OR: 1.31), EtCO2 (OR: 1.32), normalized tidal volume (OR: 2.24), and driving pressure (OR: 1.39) (Table 1, Fig. 2).

**Table 1 (abstract 001627)** Multivariate logistic regression analysis for predicting physiological subphenotypes in ARDS patients

| Predictor | Multivariate model | | | | |
|---|---|---|---|---|---|
| | *β* | *p*-value | OR | 95% CI lower | 95% CI upper |
| Respiratory rate (rpm) | 0.269 | < 0.001 | 1.309 | 1.184 | 1.448 |
| EtCO2 (mmHg) | 0.28 | < 0.001 | 1.324 | 1.189 | 1.473 |
| Tidal volume (ml/kg/PBW) | − 0.806 | 0.012 | 0.446 | 0.238 | 0.838 |
| Driving pressure (cmH2O) | 0.33 | < 0.001 | 1.391 | 1.158 | 1.67 |

β: Beta coefficient, OR: Odds ratio, CI: Confidence Interval. PBW: Predicted Body Weight. Statistical significance set at $p < 0.05$

The ROC curve of the model had an area under the curve of 0.91, with a cut-off point of 15.92. This cut-off score demonstrated a sensitivity of 0.75 and specificity of 0.94 in discriminating physiological subphenotypes (Fig. 3).

**Conclusions:** The proposed score offers a practical and robust tool for physiological subphenotyping of ARDS. This approach could facilitate personalized treatment selection and improve clinical outcomes in ARDS patients. Moreover, this method is multivariate, bedside, easy to use, and operator-independent, ensuring rapid and reliable results at the point of care. This approach underscores the importance of physiological subphenotyping in ARDS management, providing a comprehensive evaluation reflecting the complexity of the disease.

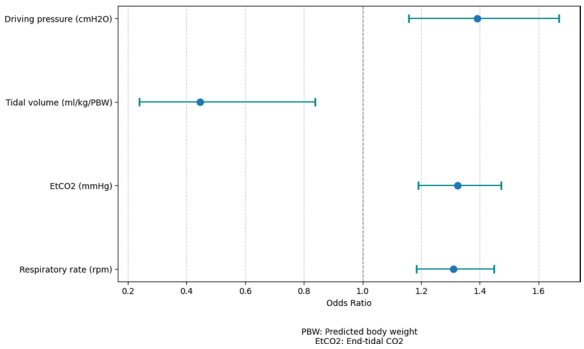

**Fig. 2 (abstract 001627)** Odds ratios of significant variables in discriminating subphenotypes: Forest plot illustrating the odds ratios of the most significant variables in discriminating between subphenotypes. Included variables are respiratory rate, normalized tidal volume, driving pressure, and end-tidal CO2 (etCO2). All variables show statistically significant differences ($p < 0.05$)

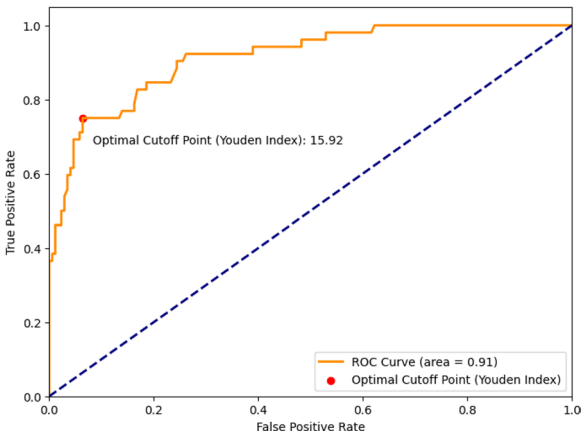

**Fig. 3 (abstract 001627)** ROC curve of ARDS Subphenotyping Score for Subphenotype 2: ROC curve illustrating the discriminative performance of the ARDS subphenotyping score in identifying subphenotype 2. The curve depicts the area under the curve and the optimal cutoff point determined using the Youden index. The curve demonstrates the model's discriminative performance in identifying the more mechanically restrictive and severe subphenotype

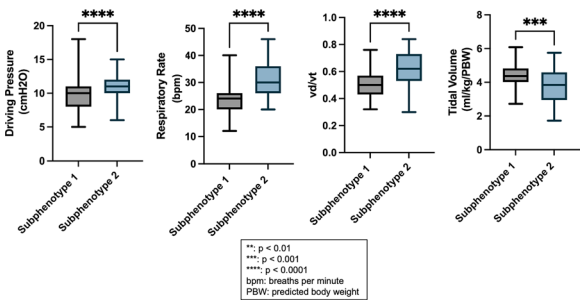

**Fig. 1 (abstract 001627)** Physiological parameters in ARDS patients: Boxplots illustrating the distribution of driving pressure, respiratory rate, vd/vt, and normalized tidal volume between subphenotypes.

Subphenotype 2 exhibits higher levels of mechanical restriction and lower ventilatory efficiency, with all differences statistically significant ($p < 0.05$)

### Videolaryngoscope (VL)-guided transesophageal echocardiography (TEE) probe insertion in intubated patients: a systematic review and meta-analysis

W. Ng[1], T. Ma[1], K.C. Leung[2], R.W.H. Hui[3], M. Zhou[1], P. Yeung Ng[4], C.W. Ngai[1], S.W.C. Sin[4]
[1]Adult Intensive Care Unit, Queen Mary Hospital, Hong Kong, Hong Kong, [2]Medicine and Geriatrics, Tuen Mun Hospital, Hong Kong, Hong Kong, [3]Department of Medicine, School of Clinical Medicine, The University of Hong Kong (HKU), Hong Kong, Hong Kong, [4]Critical Care Medicine Unit, The University of Hong Kong (HKU), Hong Kong, Hong Kong
**Correspondence:** W. Ng
***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001630

**Introduction:** Transesophageal echocardiography (TEE) has emerged as an integral tool in evaluation of critically ill patients, who are often sedated and intubated. Insertion of TEE probes in these patients can be difficult and may cause trauma to oropharyngeal mucosa from multiple attempts. The use of video laryngoscopes (VL) to assist placement has been increasingly studied. We conducted this meta-analysis to assess complications and success rates of TEE probe insertion in VL-guided approach as compared to a conventional approach.
**Methods:** MEDLINE, Embase and CENTRAL databases were systematically searched from inception to April 12, 2024, for Randomized Controlled Trials (RCTs) evaluating the use of VL-guided versus either Macintosh-guided or blind insertion of TEE probe in intubated patients. The primary outcome was the incidence of pharyngeal injury. Secondary outcomes included success in the first attempt, overall success in probe insertion, and duration of probe insertion. Random-effects model was adopted for meta-analysis. Study quality was assessed using the Cochrane Risk of Bias 2 tool (RoB2).
**Results:** This meta-analysis included 4 RCTs from 2016 to 2024 with a total of 645 patients. VL-guided TEE probe insertion led to a significantly lower incidence of pharyngeal injury (OR 0.26, 95% CI 0.13–0.52, $p = 0.0002$, $I2 = 34\%$). Operators using the VL-guided approach were more likely to succeed at the first attempt (OR 4.75, 95% CI 2.39–9.43, $p < 0.00001$, $I2 = 42\%$) and to achieve overall success (OR 12.57, 95% CI 1.04–151.83, $p = 0.05$, $I2 = 26\%$) in TEE probe insertion. However, the time required for successful TEE probe insertion was not statistically significant between the groups (Mean difference − 4.47 s, 95% CI − 20.83–11.88, $p = 0.59$, $I2 = 97\%$).
**Conclusions:** Our meta-analysis showed that VL-guided TEE probe insertion in intubated patients significantly reduced the occurrence of pharyngeal injury and increased the success rate of probe insertion at the first attempt and in overall attempts.

### Arterial blood gas analysis: effects of analysis delay

E.A. Kristinsdottir[1], M.I. Sigurðsson[2], S. Kristinn[2], S. Statkevicius[1], M.E. Broman[1]
[1]Department of Perioperative and Intensive Care, Skåne University Hospital Lund, Lund, Sweden, [2]Department of Anaesthesiology and Intensive Care, Landspitali University Hospital, Reykjavík, Iceland
**Correspondence:** E.A. Kristinsdottir
***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001631

**Introduction:** The results of arterial blood gas (ABG) analysis can be affected by several pre-analytical factors, including time from sample collection to analysis. This is primarily believed to be caused by the continued metabolism of the cells in the blood sample. Prior research on the effects of analysis delay has yielded inconclusive results and the acceptable delay time is unknown.
**Objectives:** To describe the changes that occur in an ABG sample when the analysis is delayed and estimate the acceptable delay time.
**Methods:** A total of 80 patients were included in the study. Two arterial blood gas samples were collected from each patient and analyzed in parallel at 0, 5, 10, 20, 30, 45, 60 and 120 min on two different analyzers. The samples were stored at room temperature between analyses. It was determined at what timepoint the parameter changes became statistically significant as well as at what timepoint the changes would be considered clinically important.
**Results:** Up until the last time interval, a rise in pO2 levels and a decrease in pCO2 levels was noted, contrary to what was expected. The change in pO2 reached the predetermined level of clinical importance at 45 min but the changes in pCO2 did not become clinically important during the 120 min studied. The levels of lactate increased over time but did not reach the level of clinical importance until at 120 min and on only one of the analyzers. The changes in HCO3- and base excess also first reached the level of clinical importance at 120 min and on only one of the analyzers. The glucose levels decreased over time but did not reach the level of clinical importance. The pH and electrolytes remained relatively stable over time and did not reach the level of clinical importance over the 120-min time period studied.
**Conclusions:** At 45 min, the change in pO2 reached the predetermined level of clinical importance, indicating that an analysis delay of up to 45 min is acceptable. However, most parameters remained reliable for even longer or for up to 120 min. Knowledge of the potential errors that might result from analysis delay can decrease the risk of incorrect interpretation of ABG analysis results in the clinical setting.

**Correspondence:** A.L. de Oliveira Manoel
***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001632

**Introduction:** The efficacy of omage-3 fatty in the treatment of severe respiratory failure remains controversial. Patients with Severe Acute Respiratory Syndrome due to Coronavirus 2 infection (SARS-CoV-2) may also develop a severe form of respiratory failure, therefore we assessed if the addition of omage-3 fatty acid to the standard of care would improve clinical outcomes of patients with SARS-CoV-2.
**Methods:** Double-blinded block stratified randomized, multicenter, clinical trial of adult patients ($\geq$18 years old) admitted with PCR-confirmed severe COVID-19 infection requiring Intensive Care Unit admission. Patients were randomly assigned to omega-3 fatty acid 2 g enterally twice daily for 28 days or until hospital discharge (whichever came first) in addition to standard of care vs standard of care alone. The primary outcome was the number of ventilator-free days. Secondary outcomes included length of ICU and hospital stay and in-hospital mortality.
**Results:** A total of 380 patients were included, 211 in the intervention group and 169 patients in the control group. Ventilator-free days were similar comparing the omega-3 fatty acid group compared to standard of care alone [mean 12.4 days (9.3–15.5) vs 11.1 (7.2–15.0), $p=0.48$). There was no difference between omega-3 fatty acid and control group care in terms of length of ICU stay (7 days for both groups) or hospital length of stay [16 days vs 15 days, $p=0.03$). Patients who received Omega-3 fatty acid had a trend toward lower mortality (4.3% vs 7.7%, $p=0.15$). In the pre-defined sub-group of critically ill patients who required mechanical ventilation (89 patients), omega-3 fatty group had a significant lower mortality compared to the control group (15.1% vs 33.3%, $p=0.04$).
**Conclusions:** In patients with SARS-CoV-2, the addition of Omega-3 fatty to standard of care did not increase ventilator-free days. However, it may decrease mortality in the sub-group of patients requiring mechanical ventilation.

**Topic:** Acute respiratory failure and mechanical ventilation

### Improved AI-based prediction of ICU mortality of sepsis patients based on change in HRV parameter upon fluid bolus therapy

R. LR[1], R. Sarkar[2], A. Sengupta[3], S. Jana[1]
[1]Electrical Engineering, Indian Institute of Technology Hyderabad, Kandi, India, [2]Respiratory Medicine and Critical Care, Medway NHS Foundation Trust, London, United Kingdom, [3]Physiology, Institute of Postgraduate Medical and Research, Kolkata, India
**Correspondence:** R. LR
***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001633

**Introduction:** Sepsis, a life-threatening organ dysfunction caused by a dysregulated host response to infection, is a major cause of mortality across globe. It is, therefore, important to analyse patient-specific efficacy of interventions such as fluid bolus therapy (FBT), a standard of care management for septic shock. At the same time, one seeks to accurately predict patient outcomes to optimally triage patients at high risk. Traditionally, severity score models including SAPS II, OASIS, and SOFA have found use in identifying high-risk patients. Patients present to the hospitals with baseline acute and chronic pathophysiological features, which, in their static values, form the basis of the above models. In addition, one may argue that response patterns to basic and routinely used therapies such as FBT can and should form part of prediction models, as a particular response to a therapeutic

intervention reflects a patient's underlying physiological reserve at the organic as well as the cellular level.

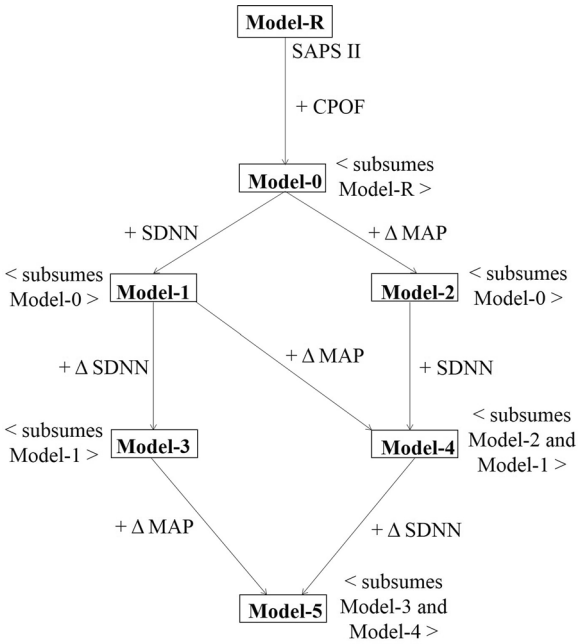
It has been established that sepsis and septic shock can cause autonomic nervous system (ANS) dysfunction. Heart rate variability (HRV) analysis, which computes statistics on time intervals between successive cardiac beats, can be used to assess ANS activity. In this scenario, we hypothesise that the prediction of mortality in sepsis patients can not only be improved by incorporating baseline HRV in the prediction model, but HRV response to FBT can also form a very strong predictive feature for sepsis morality.

**Objectives:** To examine the role of heart rate variability (HRV) changes in response to fluid bolus therapy (FBT) on mortality prediction among sepsis patients in critical care.

**Methods:** Adult patients diagnosed with sepsis in the Medical Information Mart for Intensive Care (MIMIC)-III and MIMIC-IV clinical database, who also had continuous ECG in the corresponding waveform database, within 48 h of ICU admission were selected for the study. All the predictive models were developed using a common AI architectural template. Each was based on an ensemble of decision trees making use of eXtreme Gradient Boosting (XGBoost). A mortality prediction model (Model-0) was built including the SAPS II score and common pool of features (CPOF) comprising age, sex, ethnicity, insurance, admission type, heart rate (HR), mean arterial pressure (MAP) and Elixhauser comorbidity score. A combination of the standard deviation of NN intervals (SDNN) as the HRV parameter, and FBT response in terms of the change in MAP (ΔMAP) as well as the change in SDNN (ΔSDNN) were then added hierarchically and also separately to Model-0 to develop additional models (Model-1 to Model-5). Finally, the performance of all the developed models was compared.

**Results:** A total of 5960 patients were initially screened and eventually 542 were included following exclusion criteria. The mean age of survivors and non-survivors is 63.29 and 68.94, respectively. The model with a baseline traditional feature set (SAPS II, CPOF and ΔMAP) was surpassed by an augmented model (Model-5) using HRV measurements (SDNN and ΔSDNN) as additional features in terms of predictive performance (AUC: 0.871 vs 0.921, maximum F1 score: 0.731 vs 0.792, indicating respective gains of 5.74% and 8.34%). In order of feature importance, following the SAPS II score, ΔSDNN superseded ΔMAP.

**Conclusions:** The ΔSDNN can be an important predictor of mortality in septic patients requiring fluid bolus and is stronger than ΔMAP. Clinicians can choose ΔSDNN as an additional bedside parameter to predict mortality risk in sepsis patients.



**(abstract 001633)** Block diagram of proposed mortality prediction scheme. (CPOF: Common pool of features which includes elixhauser score, age, insurance, gender, ethnicity, admission type, HR, MAP; SDNN: Standard deviation of NN intervals (NNI); FBT: fluid bolus therapy; HR: heart rate; MAP: mean arterial pressure; ( ΔMAP: Change in MAP; ΔSDNN: Change in SDNN; The baseline model (Model-R) was developed using SAPS-II as the foundational feature.)

### Extracorporeal circulation-induced hemolysis and endothelial dysfunction are associated with acute kidney injury in a rat model

C. Volleman[1], D. Dubelaar[2], R. Ibelings[3], A. Tuip-De Boer[3], C. Polet[3], M. Van Meurs[4], A.P.J. Vlaar[1], C. Van Den Brom[1]

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001634

**Introduction:** Hemolysis affects 15–21% of patients supported with extracorporeal membrane oxygenation (ECMO) [1, 2] and is associated with acute kidney injury (AKI) and mortality [3, 4]. Hemolysis is characterized by an increase in cell-free hemoglobin (CFHb), which can activate the endothelium [5, 6, 7]. Concurrently, ECMO is associated with a pro-inflammatory state that may contribute to endothelial dysfunction, subsequently leading to AKI. Nonetheless, the mechanism of hemolysis-induced endothelial dysfunction and its association with AKI during ECMO remains poorly understood.

**Objectives:** To determine the occurrence of hemolysis and endothelial dysfunction during extracorporeal circulation in rats and to assess the relation with AKI.

**Methods:** Rats were subjected to 75 min of extracorporeal circulation (ECC) or underwent a sham procedure ($n=8$). Renal vascular leakage and edema were assessed by FITC-labeled dextran extravasation (70 kDa) and wet-to-dry weight ratio, respectively. Markers related to hemolysis, inflammation, endothelial activation and renal injury were measured in blood, plasma and urine using enzyme-linked immunosorbent assay or Luminex.

**Results:** ECC resulted in elevated levels of CFHb (1.03 [0.88–1.42] vs. 0.69 [0.47–0.89], $p=0.04$), metHb (1.5 [0.8–2.1] vs. 0.3 [0.3–0.3] %, $p=0.03$) and unchanged concentrations of haptoglobin (677 [626–918] vs. 620 [505–750] pg/mL, $p=0.40$) compared to controls. Levels of lactate dehydrogenase were increased 60 min after ECC compared to controls (0.029 [0.023–0.040] vs. 0.002 [0.001–0.003] U/mL, $p<0.001$). Additionally, plasma levels of TNF-α (7.6 [6.7–10.0] vs. 0.2 [0.1–0.3] ng/mL, $p=0.008$), interleukin-6 (2.0 [1.5–2.9] vs. 0.4 [0.4–0.5] ng/mL, $p=0.008$) and angiopoietin-2 (96 [76–138] vs. 0 [0–0] ng/mL, $p<0.001$), but not ICAM-1 (38 [28–43 vs. 27 [24–33] ng/mL, $p=0.26$) increased over time during ECC. Renal dextran extravasation was similar (0.49 [0.26–0.61] vs. 0.34 [0.15–0.63] µg/mg, $p=0.57$) whereas renal wet-to-dry weight ratio was increased in rats on ECC (4.5 [4.3–4.7] vs. 4.0 [3.9–4.0], $p=0.001$). Furthermore, plasma NGAL, a biomarker of AKI, increased following one hour of ECC (1710 [1367–2787] vs. 383 [278–569] ng/mL, $p<0.001$) and was significantly elevated in urine samples when compared to controls (1733 [828–3157] vs. 437 [314–577] ng/mL, $p=0.006$). We found a positive relationship between CFHb and angiopoietin-2, though not significant ($p=0.12$). However, increased angiopoietin-2 was associated with higher levels of urinary NGAL ($\beta=52.8$, $R2=0.87$, $p<0.001$) in rats on ECC.

**Conclusions:** ECC in rats results in hemolysis, inflammation, endothelial dysfunction and renal injury compared to control animals. Interestingly, endothelial dysfunction is associated with renal injury. Future research should elucidate the role of hemolysis in endothelial dysfunction, in our model and in ECMO patients, to gain a better understanding of the pathophysiology of AKI during ECC.

### Prediction of successful liberation from continuous renal

**replacement therapy using a novel biomarker in patients with acute kidney injury after cardiac surgery—an observational trial**

J. Tichy[1], A. Hausmann[1], J. Lanzersdorfer[1], S. Ryz[1], L. Wagner[2], A. Lassnigg[1]

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001635

**Introduction:** Acute kidney injury (AKI) is with an incidence of up to 40% the most common complication following cardiac surgery (1) and leads to initiation of continuous renal replacement therapy (CRRT) based on e.g. quantitative or qualitative insufficient urinary output. Still there is insufficient evidence when CRRT should be discontinued. (2) Proenkephalin A 119–159 (PENK) is a novel biomarker reflecting kidney function independently. (3–5).
**Objectives:** Our aim was to investigate if PENK can guide a successful liberation from CRRT (no need for CRRT in the following 7 days) in patients with AKI after cardiac surgery.
**Methods:** Methods We performed a prospective, observational, single-center study at the Medical University of Vienna between July 2022, and May 2023. We included all adult patients after cardiac surgery operated on cardiopulmonary bypass, only patients on preoperative RRT were excluded. EDTA blood samples were collected and tested using the IB10 sphingotest penKid immunoassay (Sphingotec GmBH, Henningsdorf, Germany) on the Nexus IB10 Analyzer (Nexus-Dx, Inc., San Diego, USA) point of care testing (POCT) device to evaluate PENK levels.
**Results:** We screened 61 patients with postoperative AKI, 20 of them gave consent and had a progression of AKI needing CRRT. CRRT was initiated for the following reasons: 10 patients (50%) had quantitative insufficient urinary output, 4 (20%) patients suffered a reduction in vigilance due to increased blood urea nitrogen, 3 patients (15%) suffered from pulmonary dysfunction and did not reach negative bilances due to their kidney impairment, 3 patients (15%) had combined problems. Patients had a mean age of 67 ± 11 years, nine (45%) of them were female, the mean EuroSCORE was 19.7 ± 15.4%, and the mean SOFA score on ICU admission was 10.6 ± 2.4. Most of the procedures were performed electively ($N = 11$, 55%), urgent indication for operation was found in three patients (15%) and six patients (30%) were emergency procedures. At the time of CRRT liberation, patients successfully liberated from CRRT had mean PENK levels of 113 ± 95.4 pmol/L compared to 290 ± 175 pmol/L ($P = 0.018$) patients unsuccessfully liberated. For the prediction of successful liberation from CRRT we found an AUC of 0.798 (95% CI, 0.599–0.997) with an optimal threshold value of 126.7 pmol/L of PENK (Youden-Index = 1.53) at the time of CRRT discontinuation (sensitivity = 0.64, specificity = 0.89).
**Conclusions:** PENK is a novel biomarker that has the potential to predict successful liberation from CRRT in patients with AKI after cardiac surgery. This prospective study found that the novel biomarker Proenkephalin reflects kidney function independently. Therefore, Proenkephalin may be used as decision guidance for successful liberation from renal replacement therapy.

### The impact of a telemedicine intervention on early sedation depth in critically ill patients—a secondary analysis of the ERIC SW-RCT

M. Goedecke[1], N. Paul[1], F. Balzer[2], S. Piper[3], C. Spies[1], S.J. Schaller[1], B. Weiss[1]
[1]Department of Anesthesiology and Intensive Care Medicine, Charité-Universitätsmedizin Berlin, Berlin, Germany, [2]Institute of Medical Informatics, Charité-Universitätsmedizin Berlin, Berlin, Germany, [3]Institute of Biometry and Clinical Epidemiology, Charité-Universitätsmedizin Berlin, Berlin, Germany

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001638

**Introduction:** Sedation is a core aspect of intensive care medicine. Although sedatives are commonly used to manage symptoms arising during mechanical ventilation, guidelines recommend light over deep sedation in the ICU [1]. Several studies have shown that the early phase of treatment is particularly important, with early deep sedation independently associated with increased long-term mortality [2,3]. Despite efforts, there remains a gap in clinical practice in achieving evidence-based sedation management [4].
**Objectives:** To explore the impact of a comprehensive telemedicine intervention on the sedation depth of critically ill patients using the Sedation Index (SI), a time-dependent measure of sedation.
**Methods:** This study is a secondary analysis of the Enhanced Recovery after Intensive Care (ERIC) study [5], a multicenter, stepped-wedge cluster-randomized trial in a German metropolitan area. Inclusion criteria for this secondary analysis were (1) patients who required intensive care for more than 24 h, (2) were over 18 years old, (3) gave consent, (4) were covered by statutory health insurance, (5) underwent sedation for at least 48 h upon admission, and (6) had at least one daily assessment of sedation depth using the Richmond Agitation-Sedation Scale (RASS). The trial-intervention consisted of a daily telemedicine round from a university telemedicine hub structured alongside predefined quality indicators of Intensive Care [6] compared to standard-of-care (no telemedicine, control).
The SI was calculated as previously published [7]. Patients with deep sedation ($SI \geq 3$) and light sedation ($SI < 3$) were compared using univariate analysis and mixed logistic regression models.
**Results:** $N = 482$ were evaluated in this secondary analysis (control: $n = 100$; intervention: $n = 382$). The Sedation Index in the intervention group was significantly lower than in the control group (Median [Interquartile Range]: 3 [1.5–4.5] vs. 3.5 [2.6–4.5]; $p = 0.014$). Patients who received the intervention had higher chance (OR 1.8 (95% Confidence Interval: 1.1–3.1; $p = 0.005$)) of receiving evidence-based, light sedation.
**Conclusions:** A comprehensive telemedicine intervention focused on quality indicators is associated with a lower SI and may facilitate early light sedation. Future controlled studies should directly assess the impact of telemedicine rounds on sedation, an important modifiable factor in the care of critically ill patients.

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001640

**Introduction:** Studies from high-income countries suggest different admission patterns, care delivery and outcomes for male and female patients admitted to intensive care units (ICUs). Such data is lacking for critically ill patients in lower-middle income countries. We aimed to evaluate the association between sex and clinical outcomes for patients admitted to ICUs in India.
**Objectives:** Among adult patients admitted to the ICU, to determine the association between sex at birth and receipt of life-sustaining therapies and clinical outcomes.
**Methods:** We conducted a cohort study of adult patients (age > 18 years) admitted to 36 ICUs contributing to the Indian Registry of IntenSive care (IRIS), between January 2019 to December 2023. The primary exposure variable was sex at birth. The primary outcome was ICU mortality; secondary outcomes were receipt of mechanical ventilation, renal replacement therapy and vasopressors. Outcomes were censored at day 28. Categorical variables are reported as counts and proportions and continuous outcomes as mean (standard deviation) or median (interquartile range). Statistical significance testing used the Chi-square, Fisher exact test or Mann–Whitney test as appropriate. Regression evaluated associations (odds ratio [OR], 95% confidence interval) between sex and clinical outcomes, adjusting for age, APACHE II score, and Charlson Comorbidity Index. Ethics approval was obtained from the institutional ethics committee.
**Results:** Among 63,981 patients admitted to ICU, 24,264 (37.9%) were female and 39,717 (62.1%) male. Median age was 60.0 (46.0, 70.0) years. ICU mortality was 10.3% and hospital mortality 23.0%. ICU mortality was higher among male (vs. female) patients (adjusted OR 1.06, 95% CI (1.00,1.12). Hospital mortality (males vs. females) was not significantly different (OR 1.06, 95%CI (0.99,1.12). Female patients were less likely to receive invasive ventilation (OR 0.84, 95%CI (0.80–0.87),

vasopressors (OR 0.94, 95% CI (0.90–0.99) and renal replacement therapy (OR 0.76, 95%CI (0.69–0.82).
**Conclusions:** In a large Indian ICU registry of adult patients, female patients were less likely to receive common life-sustaining therapies and were more likely to survive ICU discharge.

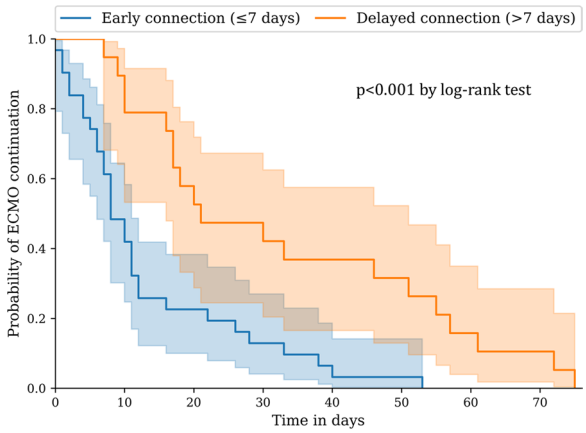
### Extended pre-ECMO mechanical ventilation—good outcome, huge burden

J. Graf[1], R. Perez[1], P. Vargas[1], R. López[1], R. Algiati[1]
[1]Departamento de Paciente Crítico, Clinica Alemana, Vitacura, Chile
**Correspondence:** J. Graf
*Intensive Care Medicine Experimental* 2024, **12 (suppl 1)**: 001642

**Introduction:** Mechanical ventilation (MV) for more than 7 days has been traditionally considered a relative contraindication for veno-venous (VV) ECMO due to observational studies prior to 2018 showing increased mortality in these patients. This recommendation has been recently challenged. In a cohort of VV ECMO patients, we compared patients connected within 7 days of invasive MV (early connection, EC) to those connected after 7 days of MV (delayed connection, DC).
**Objectives:** The primary objective is to determine if the duration of pre-ECMO MV independently affects hospital and long-term mortality. Secondary objectives are to compare complications, duration of ECMO and ICU stay between patients with EC and DC.
**Methods:** Single-center retrospective cohort study. We included all patients on VV ECMO at Clínica Alemana de Santiago between February 2017 and August 2023. Patients on ECCO2R and VAV ECMO were excluded. Demographic, physiological variables and severity scores were assessed prior to ECMO connection. Complications during ECMO, duration of ECMO and ICU stay were recorded. Survival was followed till 09/30/2023. Local IRB waived patient consent. Variables are presented as median [IQR]. Univariate analysis comparing patients according to vital status and pre-ECMO MV duration categories was performed using Mann–Whitney *U* and Fisher exact test. Kaplan–Meier time-to-event analysis comparing EC and DC groups and a multivariate Cox regression analysis for long term mortality including pre-ECMO MV duration as independent variable were performed. Significance was set at $p < 0.05$.
**Results:** 52 patients were included, 33 had COVID-19, 10 died in-hospital; 33 had EC and 19 DC. Pre ECMO MV was 2 [1–4] and 12 [9–15] days ($p < 0.01$); hospital mortality was 24.2% and 10.5%, respectively ($p = 0.293$). Those who died had higher APACHE II (17.5 [10–23.3] vs 10 [1–14] points, $p < 0.01$) and lower RESP score (0.5 [-3–2.3] vs 2 [0–4] points, $p = 0.03$), but severity scores were not different between EC and DC groups. Patients were followed for 820 [248–1126] days; 2 more patients died after hospital discharge, one from each group. Survival analysis revealed no difference between groups (log-rank $p = 0.418$). In a model including pre-ECMO MV duration, APACHE II and RESP scores, the hazard ratio for long-term mortality of pre-ECMO MV duration was 0.944 [95% CI: 0.846 to 1.05] ($p = 0.307$) for each additional day. Patients with DC had longer ECMO runs (21 [16–55] vs 10 [5.5–24] days, $p < 0.01$; Fig. 1), and ICU length of stay (56 [47–118] vs 31 [13–57] days, $p < 0.01$) than those with EC. Patients with DC also developed more hypofibrinogenemia and/or thrombocytopenia (68% vs 36%, $p = 0.026$) and required more tracheostomies (84% vs 39%, $p < 0.01$) than those with EC.
**Conclusions:** Pre-ECMO MV duration had no effect on long term mortality in VV ECMO patients. Patients with DC to VV ECMO had longer ECMO runs and ICU stays with a more complicated course than those with EC. It is uncertain if these observations pertain only to COVID-19 patients.



**(abstract 001642)** Kaplan–Meier estimates of ECMO continuation probability with 95% confidence intervals according to the duration of pre-ECMO mechanical ventilation categories. The analysis excludes two outliers from the early connection group ($n = 50$; early connection $n = 31$, delayed connection $n = 19$ patients)

**Introduction:** The production of amphiregulin, a tissue repair growth factor encoded by the *AREG* gene, is upregulated in the leucocytes of septic neonates1. In the same cohort higher plasma levels of amphiregulin accurately identified septic individuals, when other inflammatory markers remained equivocal. In murine models of influenza infection, administration of recombinant amphiregulin can ameliorate lung inflammation and reduce mortality2,3. This evidence raises the question whether amphiregulin could be predictive of severe infection, and whether its modulation may have a therapeutic role. The role of amphiregulin in adult sepsis and critical illness in unknown.
**Objectives:** This work aimed to determine the relationship between serum concentrations of amphiregulin and mortality in an adult intensive care population.
**Methods:** A single-centre, prospective, observational study. Blood samples were drawn from adult intensive care unit (ICU) patients with sepsis within 7 days of ICU admission. We collected clinical and laboratory data (including bilirubin, creatinine, CRP, lactate, lymphocyte count, monocyte count, neutrophil count, neutrophil/lymphocyte ratio, platelets and total white cell count). Serum immune parameters (amphiregulin [AREG], GM-CSF, IFN-a2, IFN-b, IFN-g, IFNl1, IFNl2/3, IL-1b, IL6, IL8, IL10, IL-12p70, IP-10, TNFa) were measured using enzyme linked immunosorbent assay (ELISA) or multiplex. Data was analysed in GraphPad Prism 10.
**Results:** A volcano plot (Fig. 1a) shows biomarkers that discriminate patients who suffered inpatient mortality versus patients who survived (FDR = false discovery rate). Serum Amphiregulin was higher among patients who eventually died, compared to patients who survived; outperforming over 20 other biomarkers in its ability to predict outcome. AREG was significantly lower in survivors versus non survivors where CRP did not discriminate (Fig. 1b) and more accurately predicted mortality (Fig. 1c).
**Conclusions:** Plasma amphiregulin concentration discriminates between ICU patients who survive or eventually die, outperforming over 20 other biomarkers tested. These findings support further investigation of the role of plasma amphiregulin in the pathophysiology of sepsis.

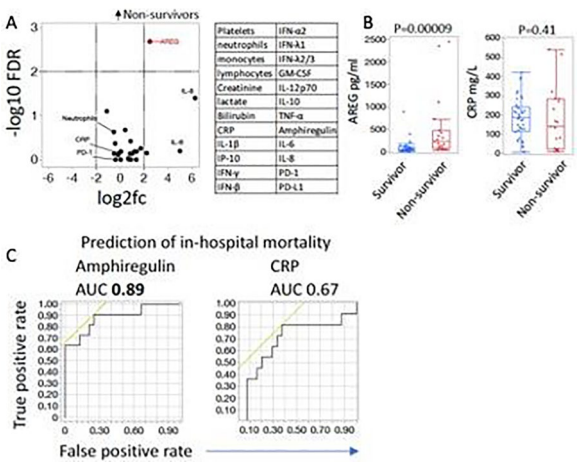

**Fig. 1 (abstract 001643)** (A) Volcano plot showing biomarkers that discriminate patients who suffered inpatient mortality versus survivors (FDR = false discovery rate). (B) Demonstrates the difference in serum amphiregulin (AREG) and C-reactive protein (CRP) between survivors and non-survivors of critical illness. (C) Demonstrates the ability of amphiregulin and CRP to predict inpatient mortality

**Introduction:** There are 34 ~ 45% of patients have intra-abdominal hypertension (IAH) in the intensive care unit (ICU). Studies have shown that in patients with acute circulatory failure and IAH, the accuracy of the passive leg raising test (PLR) to predict fluid responsiveness may be questioned.
**Objectives:** This study aims to compare the predictive performance of PLR, end-expiratory occlusion test (EEOT) and mini-fluid challenge (mini-FC) in patients with IAH and non-IAH to predict fluid responsiveness.
**Methods:** This was a two-center, prospective, observational study. Patients with acute circulatory failure who needed mechanical ventilation support in two ICUs of tertiary hospitals in China were screened. Patients who require fluid therapy as assessed by charged clinician were included. Patient were monitored by transpulmonary thermodilution device (PULSION Medical Systems SE, Feldkirchen, Getinge, Schweden). We performed consecutively 1-min PLR, 15-s EEOT, and 1-min mini-FC in all patients, and the changes in CI of the patients during each test were monitored. After completing the mini-FC test, all patients underwent a 400 mL fluid challenge during 15 min. The presence of fluid responsiveness was defined as a CI increase of $\geq$ 15% after fluid challenge. According to intra-abdominal pressure (IAP), patients were divided into IAH group (IAP) $\geq$ 12 mmHg and non-IAH group (IAP < 12 mmHg).
**Results:** From March 2023 to March 2024, a total of 74 patients were included. The median age was 61 (49,72) y.o., and 76% were male. The main cause ICU admission was infectious diseases and the median SOFA score was 12 (9,15). Among them, 82% of patients were treated with norepinephrine; 77% had sepsis/septic shock and the median arterial blood lactate level at the time of inclusion was 2.3 (1.2, 4.0) mmol/L. In IAH group (17 $\pm$ 3 mmHg), 17 patients were fluid responsiveness and 19 patients were fluid non-responsiveness. In non-IAH group (9 $\pm$ 2 mmHg), 22 patients were fluid responsiveness and 16 patients were fluid non-responsiveness. In non-IAH group, the area under the receiver operating characteristic curve (AUROC) of PLR for predicting fluid responsiveness was 0.96 (0.83–1.00), sensitivity: 90% (70%-99%), specificity: 93% (68–100%) with cut-off value of 9%. In

IAH group, the AUROC of PLR was 0.74 (0.57–0.87), sensitivity: 59% (33–82%), specificity: 84% (60–97%), with the cut-off value of 5%. The AUROC of PLR is significantly lower in non-IAH group compared to that in IAH group ($p = 0.02$). There was no statistical difference regarding the AUROC of EEOT in predicting fluid responsiveness between the two groups of patients (0.91 (0.78–0.98) vs. 0.87 (0.72–0.96), $p = 0.59$). There was also no statistical difference in AUROC of mini-FC between these two groups (0.95 (0.83–1.00) vs. 0.88 (0.72–0.96), $p = 0.41$).
**Conclusions:** In mechanically ventilated patients with acute circulatory failure, PLR has limited value in fluid responsiveness prediction in patients with IAH, while EEOT and mini-FC may be reliable alternative tests.

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001645

**Introduction:** The hemoperfusion device CytoSorb® has been proposed to remove cytokines [1] as well as excess myoglobin and bilirubin [2] from the circulation, even though its clinical relevance is still under debate [3]. Given its adsorptive characteristics being unselective for hypophilic middle molecules, we analyzed its effectiveness in other, rare indications. On one hand, as therapeutic option in Immune effector cell-associated neurotoxicity syndrome (ICANS), a common complication of Chimeric antigen receptor T-lymphocytes (CAR-T) therapy [4]. This complication arises due to an overwhelming immune response with high cytokine levels, including Interleukin-6 (Il-6), which can theoretically be reduced through hemoperfusion (Patient A). On the other hand, CytoSorb's use in decompensated pulmonary hypertension due to intravascular hemolysis. Free hemoglobin inactivates nitric oxide and consequently leads to a precapillary pulmonary hypertension [5], thus we analyzed Cytosorb's adjuvant efficiency in reducing the requirement of vasoactive medication and oxygen through removal of free hemoglobin (Patient B).
**Objectives:** Explorative retrospective analysis to evaluate CytoSorb's efficacy in reducing Il-6 levels in ICANS and free hemoglobin in hemolysis with complicating decompensated pulmonary hypertension. Correlation with clinical markers of disease/symptom severity.
**Methods:** Consent to use anonymized data was given by the patients upon admission. As soon as the diagnosis of ICANS was made, Patient A received high dose steroid treatment according to institutional standards. The clinical state of Patient A deteriorated and excessive plasma Il-6 levels were measured. CytoSorb was connected in series with a running continuous renal replacement treatment. Plasma samples for Il-6 analysis were taken at the start and then at hourly intervals during 3-h treatment duration of two filter cycles, both systemically and post-CytoSorb. Clearance rates were calculated as CI = Q x (Csyst – Cpost) / Csyst.
Patient B presented with a decompensated Cor pulmonale requiring urgent circulatory support through a VA-ECMO. When intravascular hemolysis with high levels of free hemoglobin was identified as triggering factor, a CytoSorb filter was added to the circuit and free hemoglobin levels were measured systemically at two-hour intervals over the course of 14 h.
**Results:** Repeated measurements showed a marked reduction of IL-6 and free hemoglobin, respectively. In Patient A we found an overall clearance of 31,78 ml/min for Il-6, with a Il-6 level going down from 2060 pg/ml in the beginning to 596 pg/ml within 7 h. Clinically, the reduction in Il-6 correlated with an improvement of the neurological status in patient A. For Patient B, the free hemoglobin level went down from1229 mg/l before the treatment to < 80 mg/l after 14 h. That correlated with a clinical improvement: by the end of the CytoSorb treatment the patient no longer needed Nitroglycerin (500 mcg/min at treatment start) and was weaned from the High-Flow oxygen therapy (FiO2 0.6, with 50 l/min flow) to receiving oxygen via nasal cannula (2 l/min).
**Conclusions:** CytoSorb might remove literally any hydrophobic middle-weight molecule from the circulation, which can have a meaningful application in the individualized care of selected patients. In this explorative analysis, CytoSorb was used to reduce a) Il-6 levels in a patient with ICANS, who significantly improved in its neurological status and b) free hemoglobin levels in a patient with a decompensated Cor pulmonale, who showed an improvement in the requirement of vasoactive medication and oxygen.

**Introduction:** Neoadjuvant chemotherapy (NACT) given prior to elective cancer surgery has cytoreductive benefits but its impact on post-operative immune function and infectious complications is unclear. We hypothesized that NACT is associated with an impaired immune cell response to infectious stimuli post- operatively, with increased post operative infections.
**Objectives:** To determine the influence of neoadjuvant chemotherapy on circulating immune phenotype response to an ex vivo infectious stimulus, and associated complications.
**Methods:** We conducted a secondary analysis of patients enrolled in a prospective observational study in which they had major elective cancer surgery and planned admission to a post-anaesthetic high dependency care unit. Routine clinical data were collected. Peripheral blood mononuclear cells (PBMCs) were isolated both immediately before and 24 h following surgery. PBMCs were stimulated with either heat-killed bacteria for 24 h to assess dynamic monocyte function, or CD3/ CD28 beads for 72 h to assess dynamic lymphocyte function. Using multi-parameter flow cytometry we assessed monocyte HLA-DR, PD-L1, intracellular cytokines (IL-1b, IL-10, TNF-a), and chemotaxis markers (CCR2, CXCR4). Additionally, CD4 and CD8 + lymphocyte cell death, markers of activation (CD28), proliferation/ maturation (IL-7R, IL-2R), and suppression (PD-1, CTLA-4). Outcomes measured included organ specific dysfunction, clinical infection, length of stay, unplanned ICU admission, and mortality.
**Results:** We included 38 patients undergoing cancer surgery, 22 (58%) of whom had received NACT. Patients in the NACT group had higher rates of post-operative cardiovascular (36% vs 6%, *p*-value = 0.05) and respiratory complications (59% vs 19%, *p*-value = 0.013), as well as a trend towards increased rates of infection (73% vs 50%, *p*-value = 0.2) and unplanned ICU admission (23% vs 0%, *p*-value = 0.061). No differences in immunophenotype were seen in unstimulated cells. Following stimulation, NACT was associated with higher expression of monocyte HLA-DR, and lower monocyte PD-L1 and IL-10. Additionally, CD4 IL-7R and CD8 CD28 expression were higher. However, chemotaxis marker CCR2 was lower among patients receiving NACT. Among patients without NACT, there was significant fall in monocyte count following surgery, but not among patients who received NACT.

**Significant groupwise differences in immunophenotype data**

| | NACT, *N* = 22 | No NACT, *N* = 16 | *p*-value |
|---|---|---|---|
| *Unstimulated, post-op sample* | | | |
| Monocyte Count | 0.7 (0.6, 0.9) | 0.5 (0.4, 0.7) | **0.020** |
| *Stimulated, pre-op sample* | | | |
| Monocyte HLADR | 8051.0 (1771.5, 14,629.8) | 969.5 (534.8, 9253.3) | **0.049** |
| CD4 IL7R | 630.0 (502.5, 753.5) | 546.0 (− 207.5, 620.5) | **0.041** |
| *Stimulated, post-op sample* | | | |
| Monocyte HLADR | 7145.5 (2,912.3, 8530.8) | 941.0 (661.0, 1840.8) | **0.025** |
| Monocyte CCR2 | 195.0 (0.1, 530.8) | 3054.5 (1145.3, 4346.8) | **0.036** |
| Monocyte IL10 | − 27.0 (− 76.9, 18.0) | 197.5 (− 0.6, 423.3) | **0.021** |
| Monocyte PDL1 | 182.5 (62.3, 358.3) | 540.5 (257.5, 722.5) | **0.043** |
| CD4 IL7R | 570.0 (480.0, 613.0) | 434.0 (− 70.9, 474.5) | **0.002** |
| CD8 CD28 | 3716.0 (3107.0, 4325.0) | 2728.0 (2624.0, 3253.0) | **0.048** |

**Conclusions:** Increased rates of post-operative complications were observed in patients who had received NACT prior to cancer surgery. However, their immunophenotypes contrasted with that seen in patients with sepsis-induced immunosuppression. Lower monocyte CCR2 and the lack of reduction in monocyte count following surgery suggest a different immune-mediated mechanism of post-operative complications.

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001647

**Introduction:** The organization of hospital activity in our environment is based on a model using two work shifts. In the morning shift (08:00 a.m. to 3:00 p.m.) in which the entire on-site medical team is concentrated and the rest of the schedule (3:00 p.m. to 7:59 a.m.; as well as the weekend) in which medical care is offered through on-call teams (physical or localized).
**Objectives:** Our objective is to evaluate patients who present with major bleeding and their prognosis based on their presentation during working hours or out of hours at a second-level hospital.
**Methods:** Retrospective observational study of patients with severe bleeding in a second level hospital from 2022 to 2024. Qualitative variables were recorded as absolute number and percentage. Quantitative ones such as median and interquartile range. In the univariate analysis, the chi-square test, Man-Witney *U* test and Sperman test were performed depending on the variables to be contrasted. A Kaplan–Meier curve was designed to analyze mortality between the two groups.
**Results:** 69 patients had major bleeding. The median age was 66.7 (52.3–75.8) years. Most of the major hemorrhages occurred during "on-call hours" 47 (68.1%) and were mainly due to traumatic bleeding 21 (30.4%). No significant differences were observed in age, personal history of the patients, vital signs, analytical parameters or length of stay. Mortality was higher in the group that presented severe bleeding outside of working hours with 23 deaths (48.9%) vs. 5 that occurred during standard hours (22.7%); OR: 3.26 (95% CI: 1.03–10.28); $p = 0.039$. (Fig. 1).

**Introduction:** With time, population pyramids have become progressively wider at the top, reflecting the ageing of the population, especially in European countries. Although several progresses have been made in chronic disease management and greater availability of less invasive forms of support, long-term morbidity and mortality rates for older patients admitted to the Intensive Care Unit (ICU) remain substantial.
**Objectives:** We aimed to study the local epidemiological and clinical outcomes of patients ≥ 80 years of age admitted to our ICU.
**Methods:** Our sample included patients in a mixed ICU model with level two and three care in a district hospital ICU from January 2018 to December 2022. All patients with age equal to or greater than 80 at admission were included. We evaluated patients' demographics, length of ICU and hospital stay, rate of ICU mortality and in-hospital hidden mortality.
**Results:** In the referred period, 2761 patients were admitted to our ICU. Our ICU median age in this period was 67 [56.0–76.0], and 16% ($n = 432$) were ≥ 80 years of age. 53.2% were admitted to level 2 treatment, usually limited to non-invasive ventilation, and only 1.2% of these were upgraded from level 2 to level 3 treatment. Most were medical admissions, generally due to infection or acute exacerbation of known comorbidities (53.7%, $n = 232$), followed by trauma patients (22.2%, $n = 96$), and then surgical patients (12% urgent surgery, 7.9% elective surgery). Mean APACHE predicted mortality of 35% (± 24.2), and SAPS II predicted mortality of 41.2% (± 25.7). The median ICU length of stay of octogenarians was 3 days [1.0–6.0] days, and the median duration of hospitalisation was 13 [7.0–13.0] days. The ICU mortality rate in the octogenarians was 26.1%, more significant than the ICU general mortality, calculated to be 19.7%. However, when considering only level 3 patients, mortality rises to 38.6% in this subpopulation. In 17.4%, an end-of-life decision was assumed, usually with a withdrawal approach. The hidden ICU mortality rate of octogenarian patients was 9.3%. In patients that survived hospitalisation episodes after ICU stay, mortality at one year was 16.8%.
**Conclusions:** ICUs have recently increasingly admitted more elderly patients, especially in mixed intensive care units. From our study, we can see that there is a higher mortality rate in this subpopulation, especially when considering a greater level of support, with a substantial hidden ICU mortality and mortality at one year. This may justify why most patients were admitted to level 2 treatment, with a small proportion escalating to level 3 treatment, avoiding inappropriate or disproportionate care and guaranteeing adequate end-of-life care. It would have also been essential to analyse these patients' morbidity and likely loss of function. Further investigation is also necessary to identify subgroups of patients that did particularly well and the accuracy of scoring systems to predict outcomes in these groups. Multidisciplinary meetings with input from palliative or geriatric medicine are vital for discussing the best care, and meetings with surgical teams are also deemed to define treatment limitations and prognosis before major surgery.

**Introduction:** Intravenous fluids are one of the most common interventions in critically ill adult patients. However, inappropriate use of fluids occurs in approximately 20% of the patients. Volume overload is very common in critically ill patients, especially in the absence of a standardized approach to volume management and removal. Little is known regarding current fluid administration practices in adult critically ill patients in Saudi Arabia. Therefore, our objective is to determine the current fluid practices in adult intensive care units (ICUs).
**Objectives:** Determine the fluid administration practices in adult critically ill patients.
**Methods:** A national, observational, point prevalence study of critically ill patients was conducted on a single chosen day for each participating site during a 3-month period in the year 2022. The study included adult patients aged ≥ 18 years admitted to any adult ICUs and received any crystalloid or colloid fluid (bolus or maintenance) during the last 24 h of the screening time point. The study was approved by the local IRB of each center. The primary outcome was to describe current practices regarding the choice and use of fluid administration by ICU clinicians.
**Results:** Overall, 65 ICUs within 18 institutions participated in the study. A total of 726 critically ill patients were screened and 239 patients were enrolled. The median screening day from ICU admission was 6 days [2–68]. The median age was 52 years [18–100], and 58.2% were male. The median APACHE II was 17 [2–51], and SOFA was 6 [2–17]. During the study period, 58.6% of the patients were on mechanical ventilation, and 9.38% were on renal replacement therapy. Crystalloid was administered as bolus and maintenance in 30.1% and 72.4% of the patients, respectively; while colloid was administered as bolus and maintenance in 13% and 10.5 of the patients, respectively. The mean total volume of crystalloid administered as bolus and maintenance was 1213 mL [300–6045], and 1778 mL [240–4800], respectively. Impaired perfusion was the most common reason for crystalloid administration (44.5%). The mean total volume of colloid administered as bolus and maintenance was 456 mL [100–2500].and 200 mL [50–400], respectively. Volume resuscitation in septic shock was the most common reason for colloid administration (37%). We found 81.2% of the patient on a positive balance.
**Conclusions:** Crystalloids are more frequently used fluid than colloids. Practice patterns of fluid administration in Saudi Arabia are consistent with international practices.

**Introduction:** High-fidelity computational models that capture key mechanisms of human pathophysiology offer a promising approach to investigate novel interventions for critical illness. In particular, they can augment the expensive, time consuming and logistically challenging work of conducting in vivo randomised control trials [1–2].
One such intervention, increasingly used in ARDS, is the use of a prone position [3]. While proning is not a novel intervention, its increased utilisation during the COVID-19 pandemic highlighted the many unanswered questions regarding its use. These questions range from when the intervention is best implemented, to the optimal duration of a proning session, to the supporting ventilation modalities which provide the most complementary effects [4–6]. Here, we present initial results on the development of a novel mechanistic cardiopulmonary model which can be used to investigate the above questions. As an initial validation, the model outputs have been compared to data from a patient with no respiratory history undergoing elective spinal surgery.
**Objectives:** To develop and validate a computational model of the physiological effect of prone positioning.
**Methods:** An established high-fidelity computational model of the cardiopulmonary system (Fig. 1) [7–8, and references therein] was adapted to capture the physiological changes that occur when patients are placed in the prone position. The model consists of 100 individually configurable alveolar compartments which allow for regional lung heterogeneity. To represent the impact of changing patient position, the alveolar units in the model needed to be given a spatial definition. Based on the work presented in [9–10], the lungs were divided into 10 coronal slices (Fig. 2). The mechanisms that lead to the regional changes due to the patient positioning were then added, considering the impact on the pulmonary circuit and alveolar compartments. To validate the model, clinical data was taken from a 68-year-old female undergoing elective spinal surgery. The patient had no respiratory history but did have a history of hypertension.
**Results:** Table 1 shows the supine and prone clinical data compared to the simulator outputs after the model was matched to the patient. The results show excellent agreement with the data points for both prone and supine positioning.

**Table 1 (abstract 001651)** Clinical Data vs Simulator Outcome for both prone and supine positions. Pmean—mean airway pressure. VT—tidal volume

| | Supine (measurement 15 min post-intubation) | | | | Prone (measurement 25 min post-proning) | | | |
|---|---|---|---|---|---|---|---|---|
| | Patient data | Model output | Absolute error | Absolute % error | Patient data | Model output | Absolute error | Absolute % error |
| PaO2 (kPa) | 33.10 | 33.04 | 0.06 | 0.18 | 27.70 | 27.88 | 0.18 | 0.65 |
| PaCO2 (kPa) | 4.62 | 4.61 | 0.01 | 0.22 | 4.21 | 4.21 | 0.00 | 0.00 |
| pH | 7.45 | 7.44 | 0.01 | 0.13 | 7.47 | 7.47 | 0.00 | 0.00 |
| Pmean (cmH2O) | 9.0 | 9.4 | 0.4 | 4.26 | 10.0 | 9.3 | 0.7 | 7.53 |
| VT (ml) | 420.0 | 418.6 | 1.4 | 0.33 | 415.0 | 416.7 | 1.7 | 0.41 |

**Conclusions:** The presented computational model is able to accurately capture the physiological changes caused by moving a patient with no respiratory pathophysiology from the supine to the prone position. The next stage of the study will extend the model to represent the effects of proning in patients with acute respiratory failure, ultimately leading to a tool that can be used to conduct research into the optimisation of prone positioning.

*Intensive Care Medicine Experimental* 2024, **12 (suppl 1)**: 001654

**Introduction:** Nosocomial pneumonia (NP), including hospital-acquired pneumonia (HAP) and ventilator-associated pneumonia (VAP), represents a complex and challenging clinical phenomenon that demands a profound understanding of epidemiological, pathophysiological, and therapeutic aspects, particularly within intensive care units. This clinical entity is further complicated by the escalating prevalence of multidrug-resistant strains causing nosocomial infections.
**Objectives:** To present the epidemiological situation and incidence of nosocomial pneumonia in the intensive care unit (ICU) of the Emergency Center at the University Clinical Center of Serbia and to identify potential predictors for the development of nosocomial pneumonia.
**Methods:** The study was designed as a retrospective cohort study that includes patients treated for three days and more from June 2023 to January 2024 at the central surgical ICU of the Emergency Center (EC) at the University Clinical Center of Serbia. All necessary data were obtained from the EC electronic information system. The primary outcomes of interest were the development of nosocomial pneumonia and mortality. Secondary outcomes were days on invasive mechanical ventilation, vasopressors, and ICU stay, as well as a hospital stay. Analytical and descriptive statistical methods were used in data processing.
**Results:** A total of 129 patients were enrolled in the study. The patient characteristics are demonstrated in Table 1. The microbiology of causative agents of NP are shown in Table 2. Of those parameters that were explored to be associated with NP, only chronic kidney disease (CKD), acute kidney injury (AKI) and invasive mechanical ventilation (IMV) have shown statistically significant differences (Table 3.). We performed univariable and multivariable logistic regression analysis (CKD, AKI and IMV); in multivariable CKD (odds ratio [OR], 2.35; 95% CI, 0.809–6.85) AKI (OR, 7.1; 95% CI, 2.08–24.04) and IMV (OR, 3.62; 95% CI, 1.37–9.58) are independently associated with the development of nosocomial pneumonia. Patients who developed NP had statistically significant higher mortality, stayed longer in the ICU and hospital, and also had more days on IMV and vasopressors (Table 4.).
**Conclusions:** Nosocomial pneumonia increases mortality and extends stay in the ICU and hospital among the patients in the ICU. Also, patients who developed NP had had more days on IMV and vasopressors. Only 7.93% of isolates did not have resistance to antibiotics, and the most frequent cause of pneumonia is *Acinetobacter spp.* CKD, AKI and IMV are independently associated with developing nosocomial pneumonia.

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001655

**Introduction:** Hemodynamic assessment of tseptic shock (SS) patients has a paramount role. A mixed shock hemodynamic profile on these patients is a frequent finding and is related to isolated and bi-ventricular dysfunction. LV Dysfunction has been extensively studied with conventional and speckle-tracking echocardiography (STE) and related to clinical outcomes. Nevertheless, the prognostic role of RV dysfunction in this population of patients has been undervalued despite its great relevance due to direct interactions with other organs and potential implications with therapeutic strategies.
**Objectives:** To assess the prevalence of RV and LV dysfunction in SS assessed by STE, which RV strain parameter better correlates to prognosis in these patients, and whether myocardial dysfunction assessed by STE is associated with ICU mortality.
**Methods:** We included consecutive patients with SS criteria undergoing mechanical ventilation and performed echocardiography in the first 24 h and a control echocardiography between day 3–5 of ICU admission.
**Results:** From January 2020 to November 2023, we included 72 patients in the analysis. Among patients, 80% were male, mean age 61 ± 12, most frequent foci of infection were lung (32%) followed by the abdomen (26%). ICU mortality was 30%, 44% of the patients had RV Failure according to conventional methods and 61% with STE. When comparing the two echo measurements STE worsening was associated with ICU mortality (mean change − 2.3) and Hospital

mortality (mean change − 2.1), with logistic regression analysis RV Dysfunction assessed by STE was associated with ICU mortality (OR = 3.23, 95% CI, 1.12–9.32, $p = 0.030$) and hospital mortality (OR = 2.86, 95% CI, 1.02–7.98) $p = 0.007$. LV STE was not associated with mortality.
**Conclusions:** Speckle tracking echocardiography seems to be more accurate to detect RV dysfunction in SS Patients than conventional methods. RVFWS impairment was associated with ICU and hospital mortality.

**Introduction:** Critically ill obese patients have anthropometric characteristics that could give them different nutritional-metabolic requirements than other critically ill patients.
**Objectives:** To evaluate the impact of caloric-protein intake in critically obese patients.
**Methods:** Multicenter prospective observational study (NCT:03634943). Adult patients who required medical nutrition therapy (MNT) were included and obese patients (BMI $\geq 30$ kg·m$^{-2}$) were analyzed. Demographic data, comorbidities, nutritional status, the average caloric-protein intake administered during the first 14 days and its complications, and outcomes, were recorded in a database (RedCAP®). Patients were classified and analyzed based on the adequacy of caloric and protein intake according to the recommendations of clinical practice guidelines. Univariate and multivariate analysis was performed using SPSS 25.0.
**Results:** 525 patients were included in the database. From those, 150 (28.6%) were obese. The caloric intake was considered inadequate (< 11 kcal/Kg/d) in 30.67% ($n = 46$), while 69.33% ($n = 104$) was adequate ($\geq 11$ kcal/Kg/d). The protein intake was inadequate (< 0.8 g prot/Kg/day) in 63.33% ($n = 95$), insufficient (0.8–1.2 g prot/Kg/day) in 31.33% ($n = 47$) and adequate ($\geq 1.2$ g prot/Kg/d) only in 5.33% ($n = 8$). Obese patients with an adequate caloric intake had a higher incidence of neoplasia (6.52% vs 23.1%; $p = 0.028$), a tendency towards lower organ failure upon admission (SOFA $8.2 \pm 3.6$ vs $7.3 \pm 3.4$; $p = 0.15$) and a higher use of parenteral nutrition (PN) (4.35% vs 22.12%; $p = 0.014$). Although the average hospital stay (days) was longer ($28.62 \pm 26.04$ vs $39.29 \pm 28.08$; $p = 0.032$), they had lower mortality in the ICU (32.61% vs 16.5%; $p = 0.046$).
Obese patients with an inadequate protein intake, in relation to those who received an insufficient or adequate intake, were younger ($60.12 \pm 13.06$ vs $67.04 \pm 12.5$ vs $67.5 \pm 17.86$ years; $p = 0.009$) and had lower use of PN (12.63% vs 19.15% vs 50%; $p = 0.027$). Obese showed a worse protein intake had a higher mortality in the ICU (25.53% vs 14.89% vs 12.5%; $p = 0.002$).
The multivariate analysis showed that obese patients with adequate caloric intake (HR:0.398; 95% CI: 0.180–0.882; $p = 0.023$) had better survival, while patients with insufficient protein intake (HR:0.404; CI 95%:0.171–0.955; $p = 0.038$) had better survival than those with inadequate intake.
**Conclusions:** In our population, an inadequate caloric-protein intake was observed according to clinical practice guidelines and this negatively impacts its evolution. Patients with an adequate caloric intake have better survival and an insufficient protein intake increases their mortality. Strategies should be developed to optimize MNT in the subgroup of critically obese patients.

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001658

**Introduction:** Pendelluft is a potentially injurious inspiratory pattern characterized by volume displacement from non-dependent to dependent lung regions during spontaneous breathing, which may lead to an increase in regional transpulmonary pressure and strain (1). It has been demonstrated an association between pendelluft magnitude and an increase in inflammatory biomarkers in acute distress respiratory syndrome (ARDS) patients resuming spontaneous breathing (2). ARDS patients are prone to develop vigorous effort, and, therefore, pendelluft, during ventilatory weaning and spontaneous breathing trials (SBT). Physiological determinants of pendelluft during an SBT and its association with an inflammatory response have not been evaluated.
**Objectives:** To determine the development of pendelluft and its physiological determinants during an SBT and to explore the potential association between pendelluft and an inflammatory response.

**Methods:** Adult ARDS patients who met the criteria for a SBT were evaluated during a T-tube trial. Pendelluft was quantified as the percentage of volume displaced from non-dependent to dependent lung regions during inspiration using electrical impedance tomography. Respiratory effort variables were obtained, including esophageal pressure swing (ΔPes) and pressure time product per minute (PTPmin). Pendelluft and physiological variables were measured at baseline (during pressure support ventilation) and during SBT each 30 min. Plasma inflammatory biomarkers were obtained at baseline and at the end of the T-tube trial. The association between pendelluft and ΔPes and PTPmin was evaluated with mixed-effect models. Correlation between pendelluft and inflammatory biomarkers was assessed with Pearson's test.
**Results:** Twelve ARDS patients were included (60 ± 12 years old, PaO2/FiO2 301 ± 93 mmHg, 8 ± 5 days of mechanical ventilation). Two patients exhibited SBT failure criteria and were reconnected to mechanical ventilation; the other 10 patients successfully completed a 2-h trial. The mean of magnitude pendelluft increased during the trial (7.6 ± 7% at baseline vs 11.9 ± 8% at 30 min of T-tube trial, $p = 0.002$) and it was associated with both ΔPes and PTPmin ($\beta = -0.699$, $p < 0.0001$ for ΔPes; $\beta = 0.0388$, $p < 0.0001$ for PTPmin). Although no differences were observed in any inflammatory biomarker between the beginning and the end of the trial, the change in frequency of ventilatory cycles with high-magnitude pendelluft (> 25% of volume displacement) between baseline and SBT was correlated with the change in IL-8 concentration (R2 0.41; $p = 0.02$).
**Conclusions:** Inspiratory effort is a determinant of pendelluft during SBT. The change in frequency of high-magnitude pendelluft is associated with the change of IL-8 during SBT, suggesting a potential impact of pendelluft in the inflammatory response of ARDS patients during spontaneous breathing.

### Effects of elevating the head of the bed and body mass index on interface pressure in the sacral and occipital regions of patients in the Intensive Care Unit

B.D.O. Larissa[1], A.C.A. Sousa[2], A.C. Cardoso Dos Santos[3], B.A. Marcos[3], V.A.D.A. Puschel[4], M. Amato[5]
[1]Nursing Coordination, Hospital das Clínicas HCFMUSP, Faculdade de Medicina, Universidade de Sao Paulo, São Paulo, Brazil, [2]Pneumology, Faculdade de Medicina da Universidade de São Paulo (FMUSP), São Paulo, Brazil, [3]Pneumology, Faculdade de Medicina da Universidade de São Paulo, São Paulo, Brazil, [4]Escola de Enfermagem EEUSP, Faculdade de Medicina da Universidade de São Paulo (FMUSP), São Paulo, Brazil, [5]Pneumology, Faculdade de Medicina FMUSP, Universidade de Sao Paulo, Sao Paulo, Brazil

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001659

**Introduction:** Patients in the Intensive Care Unit, especially those using invasive mechanical ventilation, have a high risk of developing pressure injuries1. Supine positioning and prolonged immobilization are the main risk factors for its development, in addition to factors related to shear, friction, nutrition and humidity2. Frequent repositioning and the use of support surfaces, which reduce and redistribute the interface pressure between the patient and the bed, are some of the strategies implemented for prevention3. Regarding the effect of body mass index (BMI) on interface pressure at different locations of bone prominences, the literature is divergent, and most studies were carried out with healthy individuals4. Furthermore, another aspect that presents divergence in the literature is the ideal degree of elevation of the head of the bed, as the need to maintain the elevation of the head of the bed from 30º to 45º has been questioned to prevent pneumonia associated with mechanical ventilation, in addition to the effects that this can cause to lung mechanics5.
**Objectives:** To evaluate the effect of different degrees of elevation of the head of the bed and body mass index on the interface pressure between the patient and the bed surface.
**Methods:** Pilot randomized clinical trial, carried out in a Respiratory Intensive Care Unit with adult patients, on invasive mechanical ventilation and eligible for ventilatory weaning at Hospital das Clinicas HCFMUSP, Faculdade de Medicina, Universidade de Sao Paulo, Sao Paulo, SP, BR. Patients were positioned in the supine position at 0°, 10°, 20°, 30° and 40°, for 10 min in each position. Interface pressure was measured continuously using the XSENSOR pressure mapping system (XSENSOR Technology Corporation, Calgary, Canada), and the sacral and occipital areas were analyzed. Sociodemographic and clinical data were acquired from the patient's electronic medical record. The study was approved by the Ethics and Research Committee of the Hospital das Clinicas HCFMUSP, protocol nº68464523.9.0000.0068. For data analysis, the linear mixed-effects model was used in the software R (R Foundation for Statistical Computing, Vienna, Austria; http://www.r-project.org), with $p$ values < 0.05 being considered statically significant.
**Results:** Data from ten patients who represented the pilot sample of the study were analyzed. 50% of participants were male. The median Braden score was 10 points and the BMI was 32.6. The average number of days intubated on the day of data collection was 3 days (SD 2.5). Regarding the interface pressure peaks identified in each region, in the horizontal supine position at 0º, the mean interface pressure was 25.7 (SD 15.8) in the occipital region and 39.8 (SD 14.6) in the sacral region, at 10º it was 24.4 (SD 14.6) in the occipital and 45.7 (SD 19.5) in the sacral, the 20th was 17.6 (SD 8.6) in the occipital and 48.1 (SD 17.9) in the sacral and the 30th was 20.3 (SD 10.4) in the occipital and 47.9 (SD 18.6) in the sacral. From the Linear Mixed Model (LMM), considering the degrees of head elevation, BMI and region as predictors, we have no evidence that head elevation changes interface pressure ($p = 0.934$), we have weak evidence of an association between BMI and interface pressure ($p = 0.063$) and strong evidence that pressure is different depending on the region, in this case, comparing the occipital and sacral regions ($p < 0.0001$). Comparing each of the 10º ($p = 0.572$), 20º ($p = 0.964$) and 30º ($p = 0.731$) decubitus positions with the horizontal dorsal decubitus position at 0º, we also have no evidence that they are different. Regarding BMI, for every 1 kg/m, the interface pressure increases by an average of 1.1 mmHg and the sacral region has a peak pressure 23.4 units higher than the occipital region on average.
**Conclusions:** In the pilot clinical trial, we did not identify evidence that the degrees of elevation of the head of the bed have a significant change with the interface pressures between the patient and the surface of the bed. We also showed a weak association between BMI and interface pressures in the sacral and occipital regions and between these regions, we obtained a significant difference in the behaviour of interface pressures. Our limitation is the sample of patients, which only included pilot cases. Furthermore, these results highlighted the importance of evaluating these aspects in critically ill patients, of considering other aspects of mechanical forces that may influence and the influence of the support surface used.

### Targeting low-value care to reduce healthcare-associated carbon emissions: Reducing the unnecessary use of intermittent pneumatic compression in intensive care

L. Hansell[1], E. Henderson[2]
[1]Planetary Health, Northern Sydney Local Health District, St Leonards, Australia, [2]Physiotherapy Department, Royal North Shore Hospital, Northern Sydney Local Health District, St Leonards, Australia

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001660

**Introduction:** 30% of carbon emissions from hospital clinical care are a result of the delivery of low-value care. Intensive care (ICU) is a major contributor to waste production. Waste associated with ICU care delivery could be reduced by identifying low-value care. Use of intermittent pneumatic compression (IPC) may be one such care practice. IPC are used in ICU to reduce venous thromboembolism (VTE) risk, but literature suggests there is no additional benefit in IPC as an adjunct to VTE chemical prophylaxis in critically ill patients.
**Objectives:** 1. Perform a carbon footprint analysis of IPC; 2. Assess change in usage of IPC prior to and following implementation of an education package to guide IPC prescription; 3. Determine waste production, greenhouse emissions and financial costs associated with changes in IPC use.
**Methods:** In this before-and-after study, the use of IPC were audited in a 58-bed level III ICU over a 3-month period, before and after the implementation of an educational intervention. Education included in-person staff education, posters, relocation of IPC stock to limit access, and an IPC prescription tool. Change in the number of IPC used, appropriateness of use, change in waste production, carbon emissions and financial cost will be reported.
**Results:** A bottom-up process-based carbon footprinting analysis was performed for IPC materials. Emissions, product weight and cost associated with a single pair of IPC were 453.44gCO2e, 124.704 g and $17.46, respectively. The audit conducted prior to educational intervention demonstrated IPC were used unnecessarily in 55.2% of cases (32/58), equating to emissions of 11.79KgCO2e, 3.99 kg of waste and a cost of $558.72 in a 3-month period. Results to date of the post-educational intervention audit demonstrate IPC were used unnecessarily in only 3 of 20 (15%) cases, equating to emissions of 1.360KgCO2e, 0.374 kg of waste and a cost of $52.38 in a 3-month period. This demonstrates an overall reduction in unnecessary use of IPC by 90.6%.
**Conclusions:** A multi-faceted approach to staff education has reduced the number of IPCs used inappropriately. This comes with greenhouse gas emissions and financial saving. Reducing low-value care provision can work to reduce the carbon footprint of low-value clinical care delivered in the ICU setting.

### Unmasking the virulence and molecular mechanisms of Infectious Endocarditis Induced by an Escherichia coli serotype O25b:H4-B2-ST131

H. Robayo-Amortegui[1], P. Flórez-Navas[1], J. Casallas[2], C. Muñoz-Diaz[3], D. Josa[4], E. Silva-Monsalve[5]
[1]Medicine, Critical Care Resident, Universidad de La Sabana, Chía, Colombia, [2]Critical Care, Fundación Clínica Shaio, Bogotá, France, [3]Center for Microbiology and Biotechnology Research (CIMBIUR), Faculty of Natural Sciences, Sede Quinta de Mutis, Universidad del Rosario, Bogotá, Colombia, [4]Genomics Laboratory, Shaio Clinic, Bogotá, Colombia, [5]Division of Infectious Disease, Shaio Clinic, Bogotá, Colombia
**Correspondence:** H. Robayo-Amortegui
***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001661

**Introduction:** Infectious endocarditis (IE) is a low-frequency disease with high mortality. Grampositive bacteria are frequently isolated from the majority of IE cases. Etiology, however, differs according to local epidemiology (1). E. coli is the most common bacteria isolated from human and animal gastrointestinal systems (2). Extraintestinal pathogenic Escherichia coli (ExPEC) is the leading cause of bacteremia worldwide, in which O serotype 25 has been reported as the most ubiquitous, and as etiology of urinary tract infections (UTI) (3). Moreover, the prevalence of Extended-spectrum β-lactamase producing E. coli (ESBL-EC) has increased in recent years (4). However, IE caused by Extended-spectrum β- lactamase producing E. coli (ESBL-EC) is rare (1,5,6) and evidence is limited, making it important to understand the physiopathologic and virulence involved in this infection (7).
**Objectives:** Describe the genomic, resistome, and potential molecular mechanisms of an ESBLEC bacteremia with a secondary IE of the native mitral valve.
**Methods:** Genomic DNA was isolated from the cultivated E. coli using a DNeasy UltraClean Microbial Kit DNA isolation kit (QIAGEN) following the manufacturer's instructions. Subsequently, it was sequenced using Oxford Nanopore technologies using the ligation sequencing kit SQK-LSK109 and a flow cell R9.4.1. Guppy tool was used to basecall Fast5 to Fastq files, quality preprocessing, and adapter removal. The Fastq file from sequencing was assembled using the Fyle v2.9 tool with default parameters. Assessment of assembly quality was performed with CheckM v1.1.3. Taxonomic assignment was performed with GTDB-Tk. Identification of molecular markers of interest, such as ARG and virulence factors, was performed using the web server of center genomic epidemiology (https://www.genomicepidemiology.org/services/), as follows: SerotypeFinder v2.0 to identify serotypes from isolates of E. coli (8), ResFinder 4.1 to identify AMG (9), VirulenceFinder 2.0 to detect acquired virulence genes (10) and PathogenFinder 1.1, a tool for prediction of a bacteria's pathogenicity towards human hosts (11). The assembly and subsequent quality assessment showed an assembly consisting of three contigs totaling 5,480,739 (5.4 Mb), which agrees with the reported size of the E. coli genome (4.5–5.5 Mb). An N50 value of 5,333,733 was found, indicating that the assembled genome was reasonably complete. The taxonomic assignment corresponding to Escherichia coli was confirmed with GTDBTk (12). The fliC gene was found with 100% of coverage and 100% identity, indicating an H_type (H4 serotype), as well as two copies of the wzx gene

with 100% of coverage and 95.79% identity, indicating an O_type (O25 serotype). Finally, this isoplate was typed as ST-131, a predominant E. coli lineage among ExPEC. However, a lost of identity (99.77%) was identified in mdh gene, being an indicator of genetic diversity.

**Results:** Understanding the importance of early, real-time genotyping and molecular characterization of E. coli strains with the potential to cause IE could represent the future of clinical practice. Knowledge of the virulome allows us to identify genes that encode virulence factors, such as adhesins (fimH, iha, AslA, papC, fdeC, hra), involved in bacterial adhesion to host tissues, facilitating the colonization of damaged areas of the valves. or the endothelium, a critical event in the onset of endocarditis. Another set of genes identified is related to iron acquisition (iucC, iutA, sitA) and genes for siderophores (fyuA, iutA, usp, yfcV), involved in the uptake and release of host iron. Since bacteria require iron for growth and replication, this ability contributes to their survival and persistence in the heart, where iron availability may be limited. These findings suggest a pathological cascade that involves direct contact with the endocardium mediated by multiple adhesion factors in E. coli, triggering an imbalance in the immune response that leads to the destruction of valvular structures and creates an environment conducive to the development of endocarditis.

**Conclusions:** IE caused by E. coli lacks detailed descriptions, particularly regarding the characterization of its virulence mechanisms. In ESBL-EC, several genes are involved in the pathological progression of IE from UTI. Understanding the importance of early and real-time molecular virulome and resistome characterization of E. coli strains in bloodstream infections could improve the risk evaluation for developing IE and maybe the future of clinical practice.

### Double cycling during partial support ventilation in hypoxemic patients resuming spontaneous breathing: is it a problem?

R. Brito[1], D. Arellano[2], C. Morais[3], A. Gajardo[1], A. Bruhn[4], L. Brochard[5], M. Amato[6], R. Cornejo[1]

**Introduction:** Double cycling asynchrony has been associated with lung and diaphragm injury in mechanically ventilated hypoxemic patients, mainly during volume- and pressure-targeted time-cycled modes.
**Objectives:** We aimed to identify double cycling with breath stacking during neurally-adjusted ventilatory assist (NAVA), proportional assist ventilation (PAV+) and pressure support ventilation (PSV) in hypoxemic patients resuming spontaneous breathing. Subsequently, to assess the risk of muscle and lung injury, we compared inspiratory effort, tidal volume, regional stretch and pendelluft magnitude in cycles with double cycling versus normal breaths.
**Methods:** Data from a crossover study of twenty patients during NAVA, PAV+and PSV (for 20-min each), were analyzed (1). Airway pressure, flow and esophageal pressure were recorded using a pneumotachometer (FluxMed MBMED®). Regional ventilation was quantified using electrical impedance tomography (EIT, Enlight 1800, Timpel Medical®). Double cycling was defined as two consecutive ventilator cycles separated by an expiratory time less than one-half the mean inspiratory time using pressure and flow waveforms (2), by experts blinded to the inspiratory effort and EIT analysis. Breath-stacking was detected when the early second insufflation occurred before complete exhalation of the previous one. We analyzed the muscular pressure (Pmus), tidal volume, regional inflation (change of impedance at non-dependent and dependent regions) and pendelluft (percentage of volume displaced from non-dependent to dependent lung regions during inspiration) in cycles with double cycling compared to an average of the 5 previous normal breaths. Analyses were performed in Stata v 14.0.
**Results:** The patients had 9 [5–14] days on mechanical ventilation. Respiratory system was 38 [30–47] mL/cmH2O and PaO2:FiO2 ratio 275 ± 46 mmHg. Tidal volume was ~ 7.4 mL/Kg PBW and PEEP 10 [7–12] cmH2O. The incidence of double cycling was lower than 1% for each mode. Only 11 patients in NAVA, 7 in PAV+and 8 in PSV presented double cycling with breath stacking. Pmus was higher in cycles double cycling compared with normal breaths in NAVA (15.0 [9.2–17.6] cmH2O vs 11.6 [8.9–13.9] cmH2O, $p = 0.003$) and PSV (13.3 [11.1–16.0] cmH2O vs 11.1 [7.7–12.8] cmH2O, $p = 0.0017$). but not in PAV+ (17.5 [13.5–21.6] cmH2O vs 14.1 [12.1–21.0] cmH2O, $p = 0.2402$). On the other hand, double cycling was not systematically associated with higher tidal volume (Fig. 1), regional stretch or higher pendelluft magnitude compared with normal breaths. Anyway, in each mode at least one cycle with double cycling and breath stacking increased tidal volume higher than 12 ml/kg IBW.
**Conclusions:** Double cycling with breath stacking is an infrequent event during NAVA, PAV+and PSV. However, in case of a higher incidence during spontaneous modes, this asynchrony could augment the risk of myotrauma more than lung injury, due to the increase in inspiratory effort and eccentric contractions.

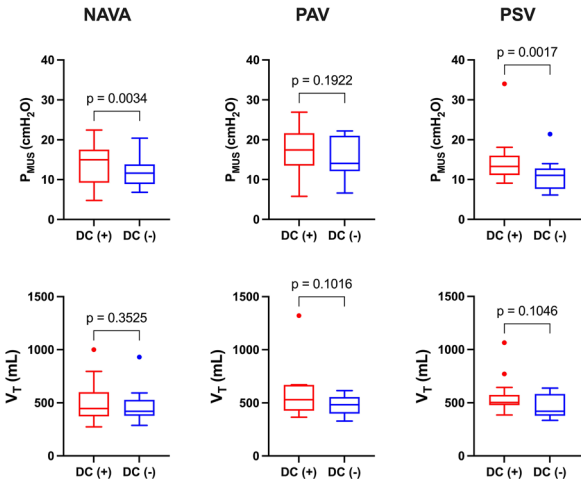

**Fig. 1 (abstract 001662)** Comparison of muscular pressure and tidal volume between cycles with double cycling and without double cycling during partial support ventilation modes. DC (+): cycles with double cycling; DC (−) cycles without double cycling; NAVA: neurally-adjusted ventilatory assist; PAV+: proportional assist ventilation; Pmus: muscular pressure; PSV: pressure support ventilation; Vt: tidal volume

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001665

**Introduction:** The Australia and New Zealand Intensive Care Society (ANZICS) adult patient database (APD) has been running for 30 years to benchmark hospital outcomes of intensive care unit (ICU) patients in Australia and New Zealand. This data allows the examination of the trends in risk-adjusted mortality and is key to planning future healthcare resources.
**Objectives:** To assess the change in risk-adjusted mortality in all ICU patients over the last 30 years and among diagnostic groups with the highest mortality rates.
**Methods:** We performed a retrospective cohort study of admission to the ANZICS APD from January 1993 to December 2022. Patient demographics, diagnosis, acute physiology and hospital outcome were extracted. All ICU admissions for adult patients (16 years) were eligible for inclusion. Readmission episodes, admissions for palliative care, intra-hospital transfers and patients with COVID-19 were excluded. Characteristics of patients were compared across the three decades using ANOVA, Kruskal–Wallis and Chi-square tests. We used mixed effects regression models adjusted for APACHE III score, hospital classification and sex to assess the adjusted odds of mortality over time.
**Results:** The final cohort included 2,838,654 patients from 209 participating ICUs. Compared to the first decade patients admitted during the final decade of the study were older (60 (SD 18.2) vs 62 (SD 17.8) years), more often had a least one major comorbidity (23.2% vs 25.2%) and had higher APACHE III scores (45.6 (SD28.1) vs 50.9 (SD 24.1)). Risk adjusted mortality fell over the study period until 2010 but then plateaued (Fig. 1). The five diagnostic groups with the highest mortality rates were, cardiac arrest 31,999/60722 (52.7%), stroke and intracranial haemorrhage 12,989/37696 (34.5%), subarachnoid haemorrhage 5775/27447 (21%), pneumonia 19,834/104028 (18.6%) and sepsis 36,073/191724 (18.8%). Cardiac arrest saw the greatest improvement in mortality OR 0.82 (95% CI 0.81 to 0.83) while pneumonia saw the least OR 0.87 (95% CI 0.87 to 0.88). The pattern of improvement for most diagnostic groups were similar, however, mortality from stroke and intracranial haemorrhage continues to improve whereas mortality from cardiac arrest appears to have increased over the past 10 years (Fig. 1).
**Conclusions:** There have been substantial improvements in risk-adjusted mortality among ICU patients in Australia and New Zealand over the past 30 years but these improvements appear to have plateaued more recently. Changes in patient factors and admission practices may be an important contributor to this finding. There is heterogeneity in the pattern of improvement according to different diagnostic groups which warrants further investigation.

### The effects of lung recruitment and inflation on intracranial compliance and autoregulation in mechanically ventilated brain-injured patients. A prospective, observational pilot study

R. Bencze[1], A. Hånell[2], H. Engquist[3], F. Freden[3], G. Perchiazzi[1], M. Pellegrini[1]
[1]Department of Anesthesia and Intensive Care Medicine, Uppsala University Hospital, Hedenstierna Laboratory, Department of Surgical Sciences, Uppsala University, Uppsala, Sweden, [2]Department of Medical Sciences, Uppsala University, Uppsala, Sweden, [3]Department of Anesthesia and Intensive Care Medicine, Uppsala University Hospital, Uppsala, Sweden
**Correspondence:** M. Pellegrini
***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001666

**Introduction:** The effect of positive end-expiratory pressure (PEEP) on cerebral perfusion and autoregulation in mechanically ventilated patients affected by acute brain-injured (ABI) has been largely debated and evidence is still not conclusive.
Invasive neuromonitoring variables as intracranial pressure (ICP), compliance (estimated by the second ICP peak, P2) and cerebral autoregulation (assessed through pressure reactivity index, PRx) can be continuously followed during mechanical ventilation.
The recruitment-to-inflation (R/I) manoeuvrer differentiate the potential of lung recruitability from the inflation of the already open lung across a standardized 10 cmH2O increase in PEEP [1]. Electrical impedance tomography (EIT) detects changes in regional distribution of gas consequent to different PEEP settings.
**Objectives:** The aim of this study was to investigate the association between lung recruitability and changes in mean ICP, P2 and PRx consequent to a delta PEEP of 10 cmH2O.
**Methods:** The study included ABI patients, requiring invasive mechanical ventilation, invasive ICP and systemic blood pressure monitoring and admitted to the neurosurgical intensive care unit (NICU) of Uppsala University Hospital, Uppsala, Sweden. Inclusion and data acquisition were performed within 72 h from ABI. During sedation, muscle relaxation and volume control ventilation (tidal volume 6–8 ml/kg predicted body weight, respiratory rate to keep the clinical target of PaCO2) and after a standardized lung recruitment, the R/I manoeuvrer was performed. Thereafter, combining the physiological background of R/I [2] and EIT, the changes in end-expiratory lung volume (ΔEELV) as well as its two components: the inflating volume (Vinfl) and the recruiting volume (Vrec), were estimated at both a global (the whole lung) and a regional level (pixelwise, based on EIT analysis) (Fig. 1A). Changes of each variable (ΔICP, ΔP2, ΔPRx) were calculated as (value at high PEEP) – (value at low PEEP), negative changes of ΔICP, ΔP2, ΔPRx indicating a worsening at low PEEP. Vrec was expressed as percentage of ΔEELV. Clinical data were collected from medical records. Data were reported as median (interquartile range). Correlations were sought using Spearman rank correlation. F-test statistics ($\alpha = 0.05$) was used for linear regression analysis.
**Results:** Ten patients were included (three females), with a median age of 62 (61–67) years. Volume recruitability was significantly correlated with ΔICP (rho = − 0.7, R2 = 0.6, $p < 0.01$), ΔP2 (rho = − 0.6, R2 = 0.7, $p < 0.01$), and ΔPRx (rho = − 0.8, R2 = 0.6, $p = 0.01$), (Fig. 1B).
**Conclusions:** The recruiting portion of lung volume gain induced by 10 cmH2O of PEEP in mechanically ventilated ABI patients affects intracranial compliance and autoregulation. The higher the potential of lung recruitment, the better intracranial compliance and autoregulation at high PEEP. R/I and EIT, together with neuromonitoring, can guide bedside assessment of the intracranial effects of PEEP.

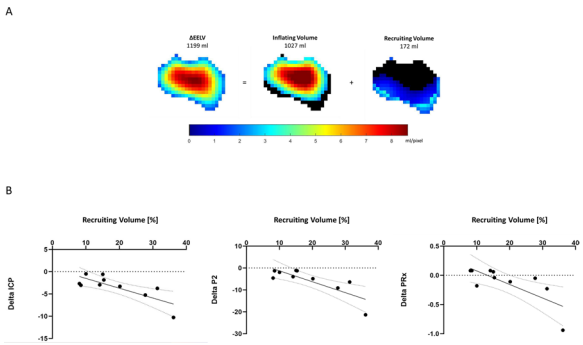

**Fig. 1 (abstract 001666)** A) Representative example of regional distribution of delta end-expiratory lung volume (ΔEELV), inflating volume (Vinfl) and recruiting volume (Vrec). ΔEELV = Vinfl + Vrec. B) Linear regressions plots between the recruiting volumes [% of ΔEELV] on the x-axis and on the y-axis: 1) left: changes in mean intracranial pressure (ΔICP); 2) middle: changes in ICP second peak (ΔP2) as index of intracerebral compliance; 3) right: changes in pressure reactivity index (ΔPRx) as index of cerebral autoregulation

### Incidence, causes and time course of moderately elevated carboxyhemoglobin (HbCO) in a large cohort of critical patients

R. Van Bommel[1], L. Polman[2], M.W. Nijsten[2]
[1]Dpt of Anesthesiology, University Medical Center Groningen, Groningen, Netherlands, [2]Dpt of Critical Care, University Medical Center Groningen, Groningen, Netherlands
**Correspondence:** M.W. Nijsten
***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001668

**Introduction:** Hemoglobin has an affinity for CO that is approximately 200 times that of oxygen. The fraction of hemoglobin bound to carbon monoxide (carboxyhemoglobin; HbCO) can now routinely measured with blood gas analysers. HbCO can be elevated in smoking, respiratory failure, resorbing hematoma, hemolysis or liver failure. The causes and kinetics of moderate HbCO increases have not been widely studied in large ICU cohorts.
**Objectives:** We explored the incidence and main causes of moderately elevated HbCO (i.e. > 5%), on ICU admission or during ICU stay. We also examined the causes of secondarily increased HbCO.
**Methods:** In a cohort of adult patients admitted to our ICU between mid 2015 and mid 2020 we examined all HbCO levels determined in blood gas samples, there were measured with point-of-care Radiometer ABL90 Flex analyzers.
We selected all patients with an HbCO > 5% that was deemed valid when repeat BGAs showed similarly elevated HbCO. Reason for admission and smoking status were recorded. In patients with ICU-acquired increase of HbCO the probable cause was sought.
**Results:** We examined 13,000 ICU patients in whom 305,000 BGAs with HbCO were determined. Overall, median (IQR) HbCO was 1.0 (0.7–1.4) %.
In 102 admissions (0.8%)—including 7 readmissions—an admission HbCO of > 5% was seen that ranged from 5.1 to 29.1%. In 4% of the cases inhalation injury was present. The other main reasons for admission were auto-intoxication (26%), severe exacerbation of COPD (chronic obstructive pulmonary disease; 20%), cardiogenic shock (18%), severe trauma (11%) and major bleeding (7%).
At least 69 of the cases (63%) were also documented smokers.
The typical half-life of the initially elevated CO was 4.5 h.
In only 7 patients (0.05%) we observed an HbCO > 5% that developed in the ICU. Of these patients, 4 were treated with extracorporeal membrane oxygenation (ECMO), 2 had complicated liver transplantation and 1 sustained severe trauma.
**Conclusions:** Moderately elevated HbCO defined as a level of more than 5% was seen in a small fraction of critically ill patients we studied. Elevated HbCO at admission was in most cases caused by autointoxication or COPD, often combined with smoking.
The half-time of correction of initially elevated HbCo is short.
Marked HbCO-elevation that is ICU-acquired is rare and mainly associated with very severe gas-exchange disorders that require ECMO or with liver failure.

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001670

**Introduction:** Prolonged mechanical ventilation (PMV) is typically described as the need for mechanical ventilation (MV) lasting at least 21 consecutive days for a minimum of 6 h per day (1). However, while the 21-day cut-off is commonly accepted, a significant portion of research on PMV employs different durations, ranging between 1 h to 1 year (2). Some authors have suggested considering MV lasting at least 14 days as PMV, especially since many studies have found that tracheostomy is often performed before the 15 days (3–4). Identifying universal risk factors for PMV has proven to be challenging due to diverse definitions of PMV, variations in study methodologies, and the heterogeneity of patient populations.
**Objectives:** To define the risk factors for PMV on the day of intensive care unit (ICU) admission.
**Methods:** A retrospective cohort study was conducted on patients admitted to a Tertiary University Medical ICU over a span of 15 years, from January 1, 2008, to December 31, 2022. The study focused on patients who required invasive mechanical ventilation (IMV),

excluding those under 18 years old, those intubated in other ICUs, individuals dependent on chronic MV, and those who died within 14 days of IMV initiation. Prolonged mechanical ventilation (PMV) was defined as IMV lasting 14 or more consecutive days. Patients were categorized into PMV (IMV ≥ 14 days) and non-PMV (IMV < 14 days) groups. Data on demographic characteristics, comorbidities, clinical and laboratory parameters upon admission were collected. A logistic regression model was employed to identify independent risk factors for PMV based on statistically significant variables.

**Results:** 1016 of 1698 patients with IMV were enrolled. Mean age was 62.5 ± 18.7 and 54.6% of patients were male. Median IMV duration was 13 days. Significant differences were observed between two groups (Table 1). The PMV group was older in age (64.1 ± 17.8 vs. 60.8 ± 19.2 years), had higher APACHE II (23.7 ± 6.8 vs. 19.7 ± 6.) and SOFA (7 [5–10] vs. 6 [4–9]), higher baseline CRP (12 [6.3–20.7] vs. 8.6 [3.1–15.3]), higher ratios of ARDS (31.3% vs. 6.8%), sepsis/septic shock (23.4% vs. 17.5%) and lower PaO2/FiO2 (176 [124–250] vs. 230 [167–310]) compared to non-PMV group. PMV patients were mostly intubated in the medical ICU (MICU) and received vasopressors on first day. In logistic regression analysis (Fig. 1), independent risk factors for PMV were: age > 65 years (OR = 1.37; CI 95% [1.02–1.83]; $p$ 0.036), APACHE II > 21 (OR = 2.05; CI 95% [1.52–2.76]; $p < 0.001$), SOFA > 7 (OR = 1.53; CI 95% [1.11–2.10]; $p$ 0.009), neurological disorders (OR = 2.02; CI 95% [1.39–2.96]; $p < 0.001$), ARDS (OR = 5.44; CI 95% [3.55–8.33]; $p < 0.001$), intubation on MICU (OR = 2.01; CI 95% [1.49–2.71]; $p < 0.001$) and CRP > 10 mg/dL (OR = 1.43; CI 95% [1.07–1.92]; $p$ 0.015).

**Conclusions:** Age > 65 years, APACHE II > 21, admission SOFA > 7, neurological disorders, ARDS at admission, intubation in medical ICU and CRP > 10 mg/dL were independently associated with PMV.

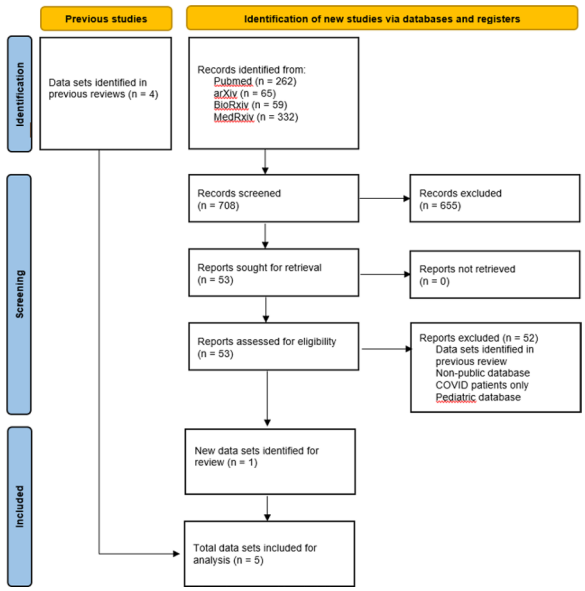
***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001672

**Introduction:** Multiple Intensive Care Unit (ICU) databases have been publicly released to advance data driven intensive care medicine. However, these public ICU datasets are prone to changes, updates and new releases. Therefore, the goal of this review is to provide clinicians and data scientists with a state-of-the-art overview and guide for choosing the relevant ICU datasets for their respective research questions.

**Methods:** A systematic search was carried out in PubMed, Arxiv, MedRxiv and BioRxiv to identify all publicly available intensive care datasets of adult patients. After data extraction of database characteristics, a qualitative synthesis of results was carried out.

**Results:** 708 publications were identified. After the screening, 5 publicly available ICU databases were included for analysis: AmsterdamUMCdb, eICU Collaborative Research Database (eICU-CRD), HiRID, Medical Information Mart for Intensive Care (MIMIC)-IV and Salzburg Intensive Care database (SICdb). A qualitative synthesis showed notable differences in number of patients, usage of organ support, admission types and frequency of measurements.

**Conclusions:** Each public ICU dataset differs due to differences in medical practice, information technologies and approach to legal restrictions. This systematic review provides clinicians and data scientists with an overview of available public ICU data sets and their characteristics.



**(abstract 001672)** Article selection process. 1 new public ICU data set was identified and included. Reporting was based on the PRISMA statement guideline for systematic reviews

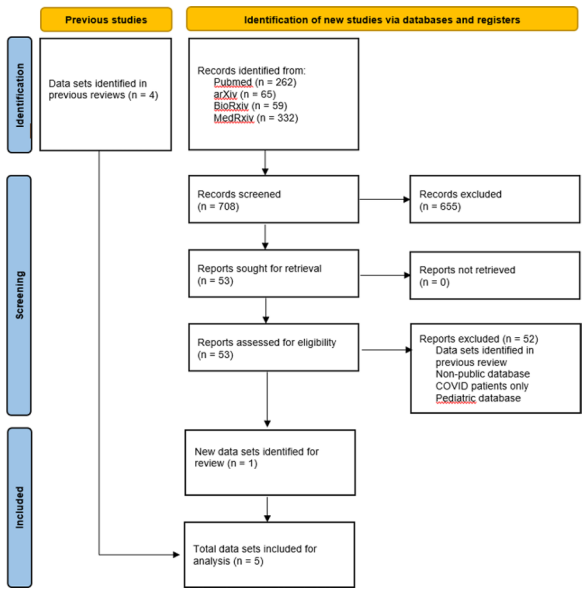


**Fig. 2 (abstract 001672)** Visual comparison of ICU data set characteristics. ALAT = alanine aminotransferase, CRP = C-reactive protein, FiO2 = fraction of inspired oxygen, PEEP = positive end-expiratory pressure, pO2 = partial pressure of oxygen

***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001673

**Introduction:** Tachycardia is independently associated with the mortality of critically ill patients. Previous studies showed a beneficial effect of beta-blockers in septic shock patients. Nevertheless, the optimal initiation time of beta-blockers is not determined.
**Objectives:** The study aimed to determine whether an early beta-blocker administration correlates with improved outcomes in a general ICU population.
**Methods:** This is a single-center, retrospective, observational study from a 56-bed ICU of a university hospital. Propensity score matching (PSM) was used to balance the baseline differences. Kaplan–Meier survival curves and Cox regression analyse were performed to analyze the 28-day hospital mortality. The primary outcome was the ability to decrease heart rate (HR) during the first week of ICU admission. The secondary outcomes include: i) the hemodynamic stability during the infusion time; ii) the hospital length of the stay (HLOS), the ICU length of stay (ICULOS), the vasopressor-free days; iii) mortality rate between early and late group. We defined an early beta-blocker initiation as starting the administration within 24 h after admission.
**Results:** From June 2016 to December 2022, a total of 1606 patients were included in the study. After PSM, 466 patients were included in analysis, with 233 in early group and 233 in late group. From the ICU admission to the initiation of beta-blocker infusion time was 10.0 (3.5, 17.6) hours in early group and 45.7 (32.8, 79.5) hours in the late group ($p < 0.001$). The median age was 55.0 (42.0, 66.8) y.o., with 34.3% of whom were females. Among them, 41.8% was admitted for sepsis/septic shock. After PSM, the baseline HR was 108.5 (102.2, 119.3) beats per minute (bpm) in early group and 109.7 (102.3, 118.8) bpm in late group ($p = 0.858$). During the first seven days of ICU admission, the HR of the early group was 5.98 (3.84, 8.12) bpm lower than that of the late group ($p < 0.001$). In addition, the percentage of HR < 95 bpm is

also significantly higher in the early group compared to the late group after 24 h. There is no difference regarding the type of beta-blocker used in these two groups ($p=0.165$) and the duration of beta-blocker use ($p=0.454$). The proportion of norepinephrine use and its doses decreased in both groups and the decline slopes of the early group are greater than the late group ($p=0.012$). There was no difference regarding the the baseline and the maximal lactate level during 72 h (Baseline: early: 3.2 (2.0, 6.0) µmol/L vs. late: 2.9 (1.8, 4.8) µmol/L, $p=0.068$); Maximal lactate during 72 h: early: 3.8 (2.2, 6.8) µmol/L vs. late: 3.1 (2.1, 5.6) µmol/L, $p=0.101$). The ICULOS and HLOS of patients in early group was 5.1 (2.3, 11.0) days and 21.0 (10.0, 37.0) days, which was shorter than that of the late group (7.1 (4.2, 12.9) days, $p<0.001$; 28.0 (16.0, 44.0) days, $p<0.001$, respectively). The vasopressor-free days was similar between two groups: early: 21.1 (0.0, 26.1) days vs. late: 22.0 (0.0, 26.4) days, respectively, $p=0.275$). The hospital mortality of patients in early group is 33.5%, similar with the late group (35.2%) ($p=0.696$). In survival analysis, there exists no statistical difference in 28-day hospital mortality compared to the early group (HR 0.77 (0.53, 1.11), Log-rank $p=0.162$). The ICU mortality is 26.6% and 26.2% two groups, respectively ($p=0.679$).
**Conclusions:** In critically ill patients with tachycardia, heart rate is better controlled in the early beta-blocker initiation group with shorter ICULOS and HLOS. Nevertheless, no survival benefit was observed for patient outcomes.

**Topic:** Cardiovascular issues in ICU

### Optimising symptom control in end-of-life care on the intensive care unit

Z. Maikovsky[1], E. Page[1], H. Roth[1], J. Laing[1], L. Hodgson[1]
[1]Internal Medicine, Worthing Hospital, Worthing, United Kingdom
**Correspondence:** Z. Maikovsky
*Intensive Care Medicine Experimental* 2024, **12 (suppl 1)**: 001674

**Introduction:** Despite a reduction in recent decades, mortality rates remain significant in UK critical care at 15–20% (1). Additionally, a further 5.9% of patients later die on the wards during the same hospital admission (2). This highlights the importance of good quality end-of-life care (EOLC) which should incorporate an individualised care plan, optimisation of symptom control and involvement of the patient and those important to them (1).
**Objectives:** To improve the provision of EOLC in the intensive care and high dependency unit (ICU) at Worthing Hospital, in particular for symptom control of patients and staff confidence in providing this care.
**Methods:** Electronic patient records (EPR) were reviewed of consecutive deaths in Worthing ICU to identify the following; use of existing EOLC documentation, prescription of anticipatory medications and specialist palliative care involvement. Two round of quality improvement have been completed with interventions in between. The interventions consisted of—creation of a new multi-disciplinary EOL care plan, the introduction of a comfort observation chart, the creation of an EOL care bundle and presenting the project at the ICU multi-disciplinary team meeting and ICU nursing training days. In addition to EPR review, the second round invluded multi-disciplinary staff survey for feedback on interventions, provision of EOLC on ICU and training.
**Results:** In the first round ($n=50$), 18% of deaths had used the pre-existing 'last days of life form', in none of these instances was the form completed fully. 41% had anticipatory medication prescribed and 6% had specialist paliaitve care involvement. In the second round ($n=42$) 21% of deaths used the EOL daily care plan. Fig. 1 outlines the differing rates of use of the comfort observation chart, prescription of symptom control medications and involvement of specialist palliative care when the EOL daily care plan was used and when it was not used.
Staff survey results ($n=16$) showed that 69% rated their confidence in looking after EOL patients as 4/5 (1 = not confident, 5 = very confident). Quantity of training amongst staff was variable, with some reporting having had no specific training on EOLC whilst others report a full day of training. Staff comments highlighted potential areas for training and development; drug management, communication and managing complex patients.
Findings were presented locally to ICU and hospital palliative care teams.
Further planned interventions include amendments to the daily care plan according to staff feedback, inclusion of EOLC provision within ICU induction for rotational staff, palliative care simulation training and creation of a link nurse role for palliative care on the unit.
**Conclusions:** Staff on ICU often look after palliative patients, however, there is scope to further optimise symptom control on the unit. Our developed electronic EOL care plan has been shown to increase the use of comfort observations, prescription of anticipatory medication and involvement of specialist palliative care services. However, uptake of the care plan is still low and further interventions are planned to increase awareness and further develop the tool. The staff survey not only identified areas for educational training but also highlighted the enthusiasm and compassion of staff to care for these patients and thus their interest to further develop their skills and understanding.

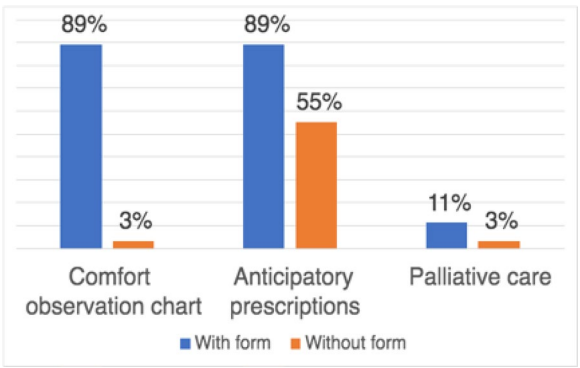

**Fig. 1 (abstract 001674)** Does the use of the EOLC daily plan improve outcomes?

**Correspondence:** T. Naito
*Intensive Care Medicine Experimental* 2024, **12 (suppl 1)**: 001675

**Introduction:** Our hospital had implemented a Rapid Response System (RRS) using a single-parameter activation criteria. To further improve the quality, from January 2023, we introduced the Visensia Safety Index (VSI), an AI-based early warning score (EWS), and nurse practitioners (NPs) conducted rounds for high-risk patients. VSI-based NPs rounds were conducted only during weekday daytime. Night-time and holidays were covered by existing RRS. This study aimed to clarify the impact of NPs rounds using VSI on in-hospital cardiac arrest (IHCA).
**Methods:** The subjects were adult inpatients who experienced IHCA from January 2023 to August 2023. Electronic medical records were retrospectively reviewed to assess the presence of pre-arrest rounds by NPs and the potential preventability of cardiac arrest. The

predictability of cardiac arrest was evaluated by two NPs and two intensivists.
**Results:** During the study period, there were 15,969 patients and 1,585 (99.3/1000 admissions) NPs rounds were activated based on VSI. There were 31 cases of in-hospital cardiac arrest, accounting for 0.2% of all inpatients. Among them, 5 out of 31 cases (16.1%) had prior VSI alerts with NPs rounds. Additionally, 2 out of 5 cases (40%) met single-parameter activation criteria before cardiac arrest. 26 out of 31 cases (83.9%) didn't have prior VSI alerts with NPs rounds before cardiac arrest. All 26 cases occurred only in the nighttime, weekends, or on holidays. Male accounted for 53.8% (14/26) and the average age was 68.7 ± 13.8 (SD). Among the 26 cases without VSI-based NPs rounds, 17 out of 26 cases (65.4%) met single-parameter activation criteria before cardiac arrest, but RRS was not activated in this population. Twelve out of 26 cases (46.2%) met VSI activation criteria when using the threshold score of 2.8. VSI criteria detected 3 out of 12 cases (25%) that could not be identified by single-parameter activation criteria.
**Conclusions:** NPs rounds using VSI could enable the identification of cases not actioned by single-parameter criteria. However, all IHCA cases where NP rounds using VSI were conducted represented intractable IHCA scenarios. Nevertheless, there were preventable IHCA cases among those without VSI alerts, indicating the need for further investigation into cases undetectable by VSI criteria.

### Evolution of admissions due to attempted suicide in the Intensive Medicine Service of the Mútua Terrassa University Hospital after the COVID-19 pandemic

I. Isern Alsina[1], J. Trenado Alvarez[1], LD. Badani Olmos[1], M. Rabaneda Vergara[1], A. Vila[1], A. Pérez-Madrigal[1], J. Puente De La Vega[1], A. Garcia[1], R. Algarte[1], B. Sanchez[1]
[1]Intensive Care Medicine, Mútua Terrassa University Hospital, Terrassa, Spain
**Correspondence:** J. Trenado Alvarez
***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001676

**Introduction:** In Spain, there has been an increase in suicides in recent years compared to previous years of the COVID-19 pandemic. It has been confirmed that during the COVID-19 pandemic there was a decrease in ICU admissions due to external causes, mainly trauma patient and suicide attempts. After the pandemic, the number of admissions due to trauma reached the previous figures but with an increase of suicide attempts as a cause.
**Objectives:** Analyze the admissions due to external causes, mainly trauma patient (with or without associated TBI) and attempted suicide, in the Intensive Care Department of the Hospital Universitari Mútua Terrassa (HUMT), before and after the COVID-19 pandemic.
**Methods:** A descriptive and retrospective study carried out between January 1, 2018 and December 31, 2023. All patients admitted to the intensive care of HUMT for external causes (trauma patient any cause and suicide attempt, for any reason), were collected. Statistics: Qualitative variables are expressed as percentages and quantitative variables are expressed as means and standard deviations (SD).: descriptive and retrospective study carried out between January 1, 2018 and December 31, 2023. All patients admitted to the intensive care of HUMT for external causes (trauma patient any cause and suicide attempt, for any reason), were collected. Statistics: Qualitative variables are expressed as percentages and quantitative variables are expressed as means and standard deviations (SD).
**Results:** 561 patients were included for external causes. Table 1 shows the main characteristics of the study population. Of the 561 patients, 492 (87%) were admitted for trauma, of these, 466 (94.7%) had an unintentional accidental cause and 26 (5.7%) were for suicide attempt (precipitate patient).
The remaining 69 (13%) patients were admitted for a suicide attempt for another cause than precipitation, 68 for drug overdose with suicidal intention and 1 for suicidal intent hanging attempt.
Figs. 1 and 2 show the total number of patients admitted by: trauma patient due to unintentional accidental cause, suicide attempts by precipitation, and drug overdose of medication (suicide attempt). In addition, in the pre-COVID period stage, 27% of the patients had a psychiatric history and 12.4% of admissions for external causes were due to attempted suicide, rising to 39% and 20%, respectively, in the post-COVID period.
**Conclusions:** In our hospital, during 2020 (the COVID-19 european pandemic period) there was a decrease in patient admissions due to external causes, this figure has been progressively increasing until reaching, in 2023, similar figures to the pre-COVID period. The main cause of this increase is suicide attempts, both due to intentional drug overdose and precipitation. Given the data obtained, we propose expanding the study to other hospitals to confirm both the situation in other sites and the trend in the coming years.

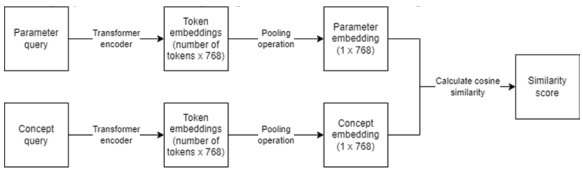
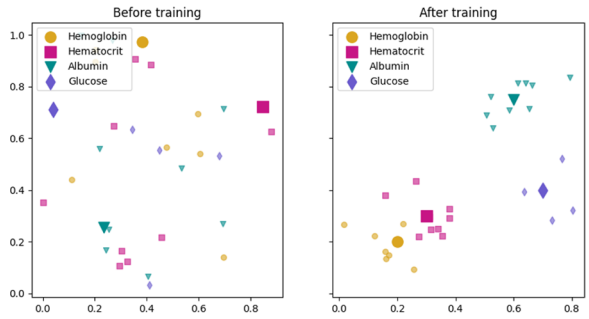
***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001677

**Introduction:** Intensive care units (ICUs) generate vast amounts of structured medical data. Harmonizing underlying databases across medical institutions is crucial for big data research. This process involves converting data formats and terminology according to a Common Data Model (CDM), enabling semantic interoperability, effective data sharing, and big data research. However, existing Electronic Health Record (EHR) systems often lack direct compatibility with CDMs, necessitating a labor-intensive manual mapping process. This challenge hinders the formation of large multi-center research databases.
**Objectives:** This study aims to address the challenges of manual data mapping in ICU databases by leveraging Large Language Models (LLMs) to create a generalized model for concept mapping, potentially reducing the time and resources needed for data unification.
**Methods:** The study involved developing a transformer model to output semantically meaningful numerical representations for parameter-concept mappings. Using the SentenceTransformers framework, the model was pre-trained on a diverse multilingual dataset and fine-tuned on manually mapped ICU datasets to improve accuracy and generalizability. The model's performance was evaluated through three experiments, comparing its accuracy with previous state-of-the-art models.
**Results:** The model achieved significant performance improvements in concept mapping. In the first experiment, using data from three hospitals, the model achieved a top-5 accuracy of 90.3%. The second experiment, with data from 26 hospitals, reached a top-5 accuracy of 93.8%. The final experiment, using a larger ICU dataset not previously seen by the model, achieved a top-5 accuracy of 86%, indicating its potential for generalization.
**Conclusions:** The transformer-based model demonstrated a notable improvement in the efficiency and generalizability of concept mapping in ICU databases. These results suggest that the approach can substantially accelerate the data unification process, enabling broader research opportunities and eventually enhancing data-driven decision-making in intensive care. Further studies should focus on extending the model's scope to other healthcare domains and languages, as well as scaling computational resources to boost performance.



**(abstract 001677)** Implementation of a sentence transformer. Token embeddings capture the contextualized meaning of a character or word within the full query



**(abstract 001677)** Simplified illustrative visualization of two-dimensional embeddings before and after training. The larger shapes represent concept embeddings, while the smaller shapes represent parameter embeddings. Before training, the embeddings are random. During training, the model gradually learns to output similar embeddings for parameters and concepts, clustering those that represent the same entity

### Evaluation of the effect of norepinephrine on cardiac contractility after the initial phase of septic shock

G. Théry[1], M. Bertrand[1], F. Jarraya[1], M. Hérisson-Garin[1], Z. Djerada[1], J.L. Teboul[2], O. Hamzaoui[1]
[1]Unité de Médecine Intensive et Réanimation Polyvalente, CHU Reims, Reims, France, [2]Faculté de Médecine Paris-Saclay, Université Paris-Saclay, Le Kremlin-Bicêtre, France
**Correspondence:** O. Hamzaoui
***Intensive Care Medicine Experimental*** 2024, **12 (suppl 1)**: 001681

**Introduction:** Norepinephrine (NE) is recommended as the first-line vasopressor in the management of septic shock. Early introduction of NE has a beneficial effect on cardiac contractility (1). This latter effect may be linked to a direct inotropic action of NE via the stimulation of myocardial β1-receptors and/or an improvement in left ventricular perfusion via increased diastolic arterial pressure (DAP). Data are lacking on whether the inotropic effect of NE persists beyond 24 h after the start of management insofar as a down-regulatory mechanism of myocardial β1-receptors could negate this effect.
**Objectives:** The aim of our study is to examine, by transthoracic echocardiography (TTE), the effects of NE dose escalation on left ventricular systolic function in hypotensive patients, more than 24 h after the Start of septic shock.
**Methods:** Prospective, single-center study (medical intensive care unit), including patients with hypotension (mean arterial pressure (MAP) < 65 mmHg) requiring an increase in NE dose, more than 24 h after the start of septic shock management. TTE was performed at T0 and T1 (one hour after restoration of MAP > 65 mmHg).
**Results:** 17 patients were included (median age 68 years [IQR, 50–78]). MedianSAPSII was 57 [43–71], 16 patients were on mechanical ventilation and septic shock was mainly of respiratory origin (10/17). Between T0 and T1, NE dose, MAP, systolic arterial pressure (SAP) and DAP increased significantly (Table 1). TTE showed a significant increase between T0 and T1 in left ventricular ejection fraction (LVEF), respectively: 56% [48–63] vs. 59% [53–65] ($p = 0.048$), and subaortic time-velocity integral ( VTI subAo): 15 cm [12–18] vs. 18 cm [16–22] ($p < 0.01$).
**Conclusions:** In hypotensive septic shock patients, increasing the dose of NE during the late phase of septic shock (more than 24 h)

corrected arterial hypotension and significantly increased VTIsubAo and LVEF. The increase in LVEF that occurs despite the increase in SAP and hence left ventricular afterload, suggests that NE improves cardiac contractility even after the initial phase of septic shock.

**Table 1 (abstract 001681)** HR, Heart rate; LVEF Left ventricular ejection fraction; VTIsubAo, velocity time integral of the subaortic-flow; MAPSE, mitral annular plane systolic excursion; DAP, diastolic arterial pressure; MAP, Mean arterial pressure; SAP, systolic arterial pressure; SV, Stroke volume.
