Abstract

The effects of the water retention curve hysteresis on concrete made from Recycled Concrete Aggregates are investigated. A multiscale multiphase FE² model is developed and validated experimentally. Properties for the calibration of the hysteresis are also obtained experimentally. A coupled chemo-hydraulic multiscale model, able to represent the chloride ingress inside the porous structure of concrete, was developed with the Finite Element squared (FE²) method. The constitutive equations are based on properties that are measured in laboratory conditions, for concrete manufactured with 100% Natural Aggregates (NA) or Recycled Concrete Aggregates (RCA), respectively. The hysteresis of the water retention curve is implemented according to the Van Genuchten formulation. Results suggest that not accounting for the hysteresis of the water retention curve introduces a significative error in the saturation degree of concrete and, therefore, in the chloride content.

1. Introduction

Durability of concrete can be defined as the ability of a structural concrete member to withstand the effect of time and degradation processes while retaining its strength for which it was designed [1]. Degradation processes can have multiple causes such as freeze-thaw cycles, carbonation, chloride attacks or, in most cases, a combination of these [2, 3]. Most of the degradation processes that take place in concrete depend on the water content of the concrete porous system. For freeze-thaw cycles, the greater the saturation degree of the material is and the greater the degradation may be. For chloride attacks and carbonation, corrosive ions require water to migrate and reach the reinforcements [4]. Furthermore, reactions of corrosion are the most critical at around 85% of saturation degree [5]. Understanding the transfer of water in concrete is therefore crucial for the evaluation of its durability.

In spite of the environmental concerns related to concrete manufacturing, the use of recycling materials is being promoted as substitute to natural materials. Recycled Concrete Aggregates (RCA) have thus been studied for many years to reduce the consumption of Natural Aggregates (NA). Unfortunately, this substitution tends to decrease the durability properties of concrete, mainly due to changes in its porous structure [6, 7, 8]. This modification of the porous system is then correlated to differences in the water transfer properties of concrete. An extensive study of water transfer properties must then be performed in order to better apprehend the effects of that substitution on durability [8].

The water content of many geomaterials, such as concrete, has been characterised through Water Retention Curves (WRC) in the literature [9, 10, 11, 12, 13, 8]. Water retention curves relate the degree of saturation of a porous medium to the environmental conditions such as the relative humidity and the temperature, through the expression of the total suction. For this definition to be valid, the theory of porous media must be applied to the porous system of concrete. That is, pores of concrete can only be filled of air, water or a mix of both. In a saturated porous medium, the pores are filled with water, whereas in an unsaturated

29 porous medium, the porous system is filled with both water and air. The theory of mixture
 30 [14, 15] is also applied to concrete. It states that all phases are assumed to occupy the same
 31 region of space simultaneously, as the superposition of different continua. It allows the mass
 32 balance equations of our model to be defined for each phase separately [14], with interactions
 33 between the constituents [15].

34 The total suction can be written through the Kelvin's law:

$$s = -\rho_w \frac{R T}{M} \ln(RH) \quad (1)$$

35 with s the matrix suction [Pa], ρ_w the water density [kg/m³], R the constant of ideal gases
 36 (equal to 8.3143 [J/K.mol]), M the molar mass of water (equal to 18.016 [g/mol]) and,
 37 finally, T and RH the temperature [K] and Relative Humidity [-], respectively. In this
 38 paper, we make the assumption that the total suction is equal to a matrix suction, that is
 39 to the difference between the air pressure and the water pressure:

$$s = P_g - P_w \quad (2)$$

40 with P_g and P_w the gas and water pressures [Pa], respectively.

41
 42 An example of WRC is given in Figure 1. The shape of the WRC depends significantly
 43 on the porous structure of the material [11, 16], and four zones are often depicted, depending
 44 on the number of phases filling the pore system and the (dis)continuous nature of said phases
 45 [11]:

- 46 1. When the suction is smaller than the air-entry pressure (denoted as α in Figure 1),
 47 then the material is completely saturated, as no air can enter the pores and therefore,
 48 no water can escape. This section is almost horizontal, and some authors refer to it as
 49 the boundary effect zone due to the local exchanges between the surface of the sample
 50 and its environment [11, 17, 16];
- 51 2. Once the suction is equal to the air-entry pressure, air can enter the porous system
 52 and the degree of water saturation decreases. This state is called the funicular state
 53 where the liquid phase is continuous and the gas phase consists of isolated air pockets.

54 This section marks the transition from the funicular state (which consisted of the first
55 two sections) to the pendular state (that is the last two sections) [11, 17, 16];

56 3. The third section is defined by discontinuous gas and liquid phases, neither being
57 continuous anymore. It is also part of the transition zone [16];

58 4. The last region observed is the residual state [16, 11], where the water saturation
59 degree is equal to the residual saturation degree, often noted $S_{r,res}$. It corresponds
60 to the water content that may never be extracted without extreme heating, such as
61 chemically bonded water.

62 A porous material such as concrete exhibits two separate water retention curves: one
63 specific for drying conditions, and another one for wetting conditions, the shape of both
64 curves being modelled as similar. Depending on the drying and wetting history of the
65 porous material, the water retention curve can follow an infinity of paths [11]: this is the
66 hysteresis phenomenon. It is often associated to multiple causes:

- 67 • The ink-bottle effect [9, 10, 19, 16, 20]: the cross section of the pores are irregular,
68 requiring a local increase in suction for the liquid phase to continue its movement.
69 The water content inside a capillary is indeed different at drying or wetting, at equal
70 suction;
- 71 • The raindrop effect [9, 10, 19, 16, 20]: the value of the contact angle is different between
72 an advancing and a receding meniscus;
- 73 • Entrapped air [21, 10, 22, 19, 16, 20]: the liquid phase is required to push the air out
74 of the porous medium prior to rewetting, which can lead to entrapped air inside the
75 material, accounting for up to 10% of the volume of a soil [10].

76 The hysteresis phenomenon is presented in Figure 2. The two main WRC, that is the
77 boundary drying curve and the boundary wetting curve, act as limits that may never be
78 crossed. In between, an infinity of scanning curves can be created, depending on the history
79 of the material [9, 19].

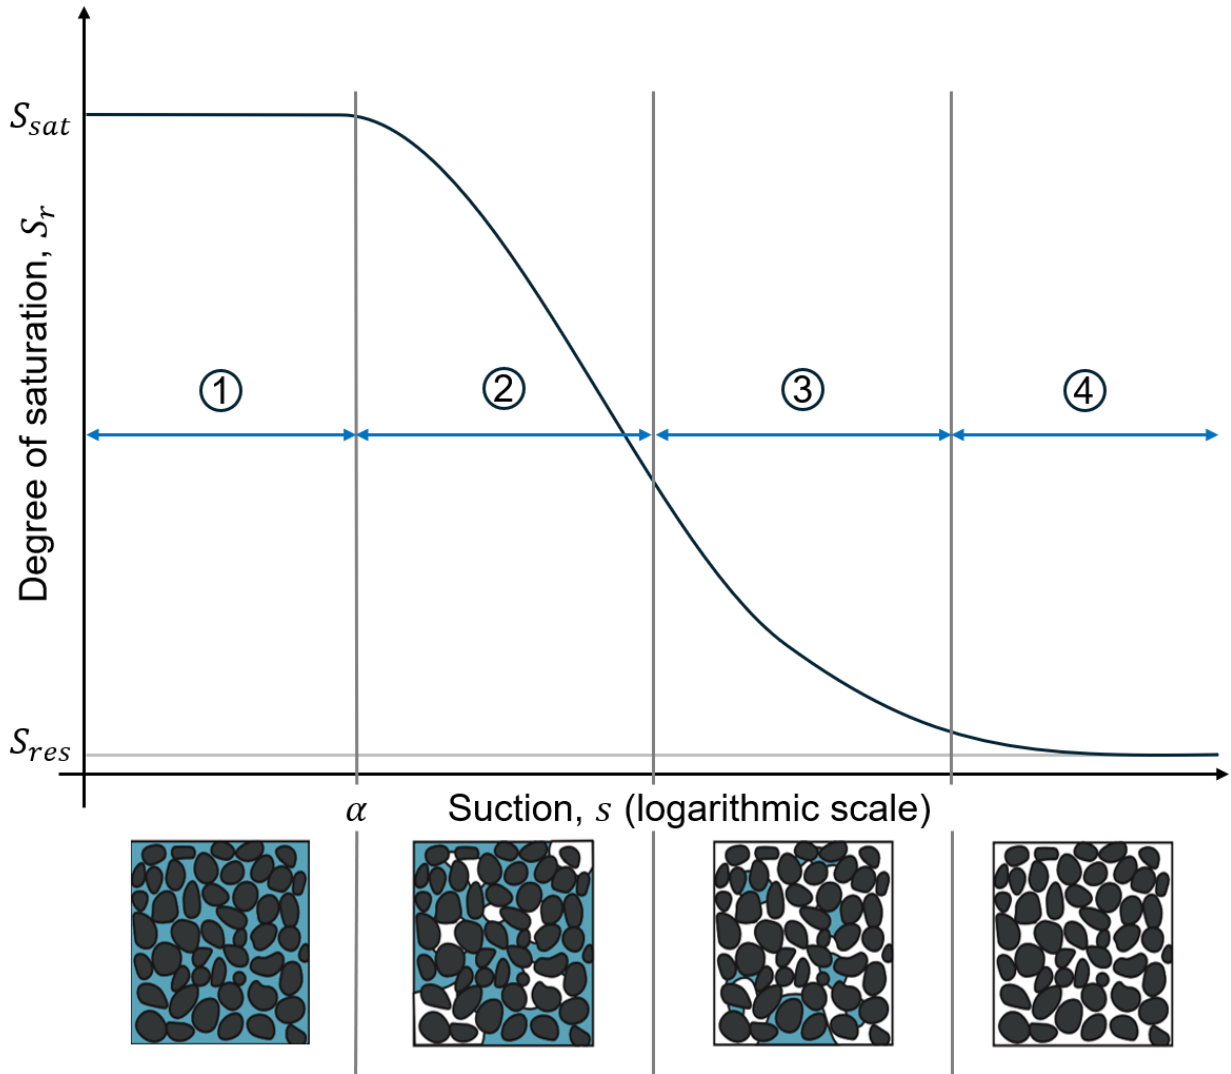

Figure 1: Typical water retention curve (modified after [11, 18])

80 The scientific community has developed many models to represent the water retention
 81 curve of geomaterials. They can be divided into two categories: the domain models (also
 82 called physically based models) and the empirical models [10, 22]. Amongst the domain mod-
 83 els, some are called dependent models or independent models [23], depending on whether the
 84 model takes into account the water content of surrounding pores or not, respectively [10].
 85 The domain models, in general, represent the porous system of a material as a collection of
 86 pore domains of specific radii, based on the domain theory of capillary hysteresis [22, 10].
 87 In that theory, the pores can only be full of water or empty, each state being assigned to a

Figure 2: Hysteresis in the water retention curve (from [9])

88 value of drying or wetting suction [10]. On the other hand, the empirical models focused on
 89 the development of empirical laws that were fitted to experimental results [10, 24]. For the
 90 empirical models, two subgroups can be observed [10]: those that use the same empirical
 91 equation for both boundary drying and wetting curves, adjusting the value of the fitting
 92 parameters accordingly [24], and those that express relationships between the two curves.
 93 An extensive comparison of 29 models based on experimental results for 34 soils has been
 94 presented in Pham et al. (2005) [10]. Unfortunately, no data is available for similar experi-
 95 ments on concrete.

96
 97 The description of the hysteresis is often neglected in numerical models, as the valid-
 98 ation of such models require experimental results, that are often hard to obtain and very
 99 time consuming. Furthermore, it increases the number of parameters describing the WRC.
 100 Hence no consensus was found in the literature on the incorporation of the hysteresis inside
 101 numerical models [22].

102 For this research, as the durability of concrete greatly depends on the saturation degree of

103 its porous system, it was decided to implement the hysteresis of the water retention curve.
104 Experimental results allowed the precise determination of the numerous parameters required
105 for the model. To better quantify the effect of the hysteresis on durability, the model also
106 incorporates the ingress of chloride ions, which can serve as an indicator of durability inside
107 reinforced concrete. Furthermore, this work is part of a study that tends to characterise the
108 influence of the substitution of natural aggregates with recycled concrete aggregates inside
109 concrete. A comparison of the hysteresis effect between the two materials is also presented.

110 **2. Materials and Methods**

111 *2.1. Materials*

112 The experimental phase of this work focused on obtaining intrinsic properties for the
113 transfer of water and chlorides inside several materials:

- 114 • a concrete made from Natural Aggregates (NA), called Natural Aggregates Concrete
115 (NAC), that comprises CEM I 42.5 N cement, 0/2 Rhine Sand and 2/7 limestone
116 aggregates;
- 117 • a concrete made from Recycled Concrete Aggregates (RCA), called Recycled Aggregates
118 Concrete (RAC), that comprises the same cement and sand than the NAC but
119 with 2/7 RCA. The RCA originate from another study made at the University of Liège
120 named SeRaMCo [25]. They consist of sandstone concrete blocks cast in the laborat-
121 ory and crushed multiple times by an impact crusher. The particle size distribution of
122 the RCA was reconstructed to be similar to that of the NA, and the substitution was
123 performed with a 100% substitution ratio at equal volume;
- 124 • an equivalent mortar, called E-M, composed of the same cement and Rhine sand than
125 the two concretes, and whose composition method was the Concrete Equivalent Mortar
126 method [26].

127 The composition and fresh properties of the three materials defined are visible in Table 1,
128 and more information on the materials may be found in Fanara et al. (2023) [27].

Table 1: Composition and fresh properties of the materials characterised:
NAC, RAC and E-M.

Composition	m_{agg} (kg/m ³)	m_{sand}	m_{cement}	m_{water}	W/C	Efficient W/C
NAC	1111	643	320	172.5	0.54	0.5
RAC	946	643	320	201.2	0.63	0.5
E-M	-	1337	622.5	336	0.54	0.54

129 *2.2. Methods*

130 The experiments performed were aimed at determining water transfer properties or chlor-
131 ide transfer properties:

132 • Water transfer properties [8]:

133 – the water absorption, dry and saturated densities, and water-accessible porosity
134 of our materials were determined according to the ASTM C 642-97 "Standard
135 Test Method for Density, Absorption, and Voids in Hardened Concrete";

136 – the water intrinsic permeability was obtained according to the NBN EN ISO
137 17892-11:2019;

138 – the parameters of the water retention curves were obtained with the vapour con-
139 trol method. This experiment is detailed in Section 2.2.1 below.

140 • Chloride transfer properties [27]:

141 – the chloride diffusion coefficient was obtained with an experiment of chloride
142 diffusion under transient conditions, following the guidelines of the NBN EN
143 12390-11 "Testing hardened concrete - Part 11: Determination of the chloride
144 resistance of concrete, unidirectional diffusion".

145 *2.2.1. Static Sorption and Desorption*

146 The Water Retention Curve can be obtained by fitting an empirical model, such as
147 the one of Van Genuchten (1980) [24] to experimental results. Experimentally, the water

148 saturation degree of a material may be linked to the suction through the expression of the
 149 Kelvin’s law (Equation 1). To obtain our boundary drying and wetting curves, the vapour
 150 control method is implemented [28], based on the hypothesis that all hygroscopic materials
 151 absorb or release water vapour depending on their water saturation degree, in order to
 152 reach equilibrium with the humid air they are in contact with: the vapour pressure and
 153 temperature inside the porous system and outside must be equal [28]. The control of the
 154 relative humidity of the ambient medium, through the use of saline solutions, and the control
 155 of the temperature through a climatic chamber, enable the acquisition of several (s ; S_r)
 156 points on the water retention curves [29, 13]. The saline solutions and their respective target
 157 suction at 21°C are shown in Table 2.

Table 2: Saline solution and their respective target RH [%] and suction [MPa] at 21°C, used for the determination of the water retention curves of our materials.

Saline Solution	KCl	NaCl	Ca(NO ₃) ₂	MgCl ₂	Silica salt
Target RH [%]	90	75	56	35	6
Target Suction [MPa]	-14.3	-39.1	-78.7	-142.5	-381

158 Samples are initially saturated, or dried at 105°C, until they reach a constant mass.
 159 Then, they are placed inside a chamber with one of the saline solutions. Each week, the
 160 mass and the ambient air parameters (RH and T) are measured. After approximately three
 161 months, the sample mass doesn’t vary considerably anymore and the sample is considered
 162 in equilibrium. Based on its mass at equilibrium and previous measurements of its dry and
 163 saturated mass, the degree of saturation can be obtained. To model the hysteresis, the
 164 samples were put in a first chamber, then after hygroscopic equilibrium and measurement
 165 of their mass, they were changed of chamber. This was repeated multiple times to obtain a
 166 noticeable hysteresis.

167 2.2.2. Modelling the Water Retention Curve hysteresis

168 The model implemented in this work is the empirical model of Van Genuchten (1980)
 169 [24] for the boundary curves, and the model of Zhou et al. (2012) [30] for the hysteresis

170 curves.

171 According to Van Genuchten, the water saturation degree is linked to the suction through
 172 the following equation [24]:

$$S_e = S_{res} + (S_{sat} - S_{res}) \left(1 + \left(\frac{s}{\alpha}\right)^n\right)^{-m} \text{ with } m = 1 - \frac{1}{n} \quad (3)$$

173 where n [-] is an adimensional model parameter related to the rate of desaturation of the soil
 174 and m [-] is another adimensional model parameter related to the curvature (slope) of the
 175 water retention curve. The last model parameter, denoted α [Pa], is related to the air-entry
 176 pressure [8]. Finally, one can see the maximum saturation degree S_{sat} [-] and the residual
 177 saturation degree S_{res} [-] [17], as well as the suction s [Pa].

178
 179 The main boundary curves of the water retention curves, defined by Equation 3, can be
 180 written specifically for the drying curve (with a suffix d) and for the wetting curve (with the
 181 suffix w):

$$S_{e,w} = S_{res} + (S_{sat} - S_{res}) \left[1 + \left(\frac{s}{\alpha_w}\right)^{n_w}\right]^{-m_w} \quad (4)$$

$$S_{e,d} = S_{res} + (S_{sat} - S_{res}) \left[1 + \left(\frac{s}{\alpha_d}\right)^{n_d}\right]^{-m_d} \quad (5)$$

182 The scanning curve (suffix s) is then defined by [30]:

$$\frac{\partial S_{e,s}}{\partial s}(\text{wetting}) = \left(\frac{s_w}{s}\right)^b \left(\frac{\partial S_{e,w}}{\partial s}\right) \text{ with } s_w = \alpha_w (S_e^{-1/m_w})^{1/n_w} \quad (6)$$

$$\frac{\partial S_{e,s}}{\partial s}(\text{drying}) = \left(\frac{s_d}{s}\right)^{-b} \left(\frac{\partial S_{e,d}}{\partial s}\right) \text{ with } s_d = \alpha_d (S_e^{-1/m_d})^{1/n_d} \quad (7)$$

183 where the parameter b [-] is defined as a fitting parameter, always positive. It influences the
 184 gradient of the scanning curve: the closer it gets to zero and the closer the hysteresis curve
 185 is to the main curve, while the greater it is and the more horizontal the hysteresis curve gets
 186 [30]. The wetting and wetting boundary curves, along with an example of a scanning curve,
 187 are shown in Figure 3.

188 The final saturation degree may then be obtained thanks to the derivative defined above
 189 and the increment of suction (ds) applied:

$$S_e^t = S_e^{t-1} + \left(\frac{\partial S_{e,s}}{\partial s}\right) \times ds \quad (8)$$

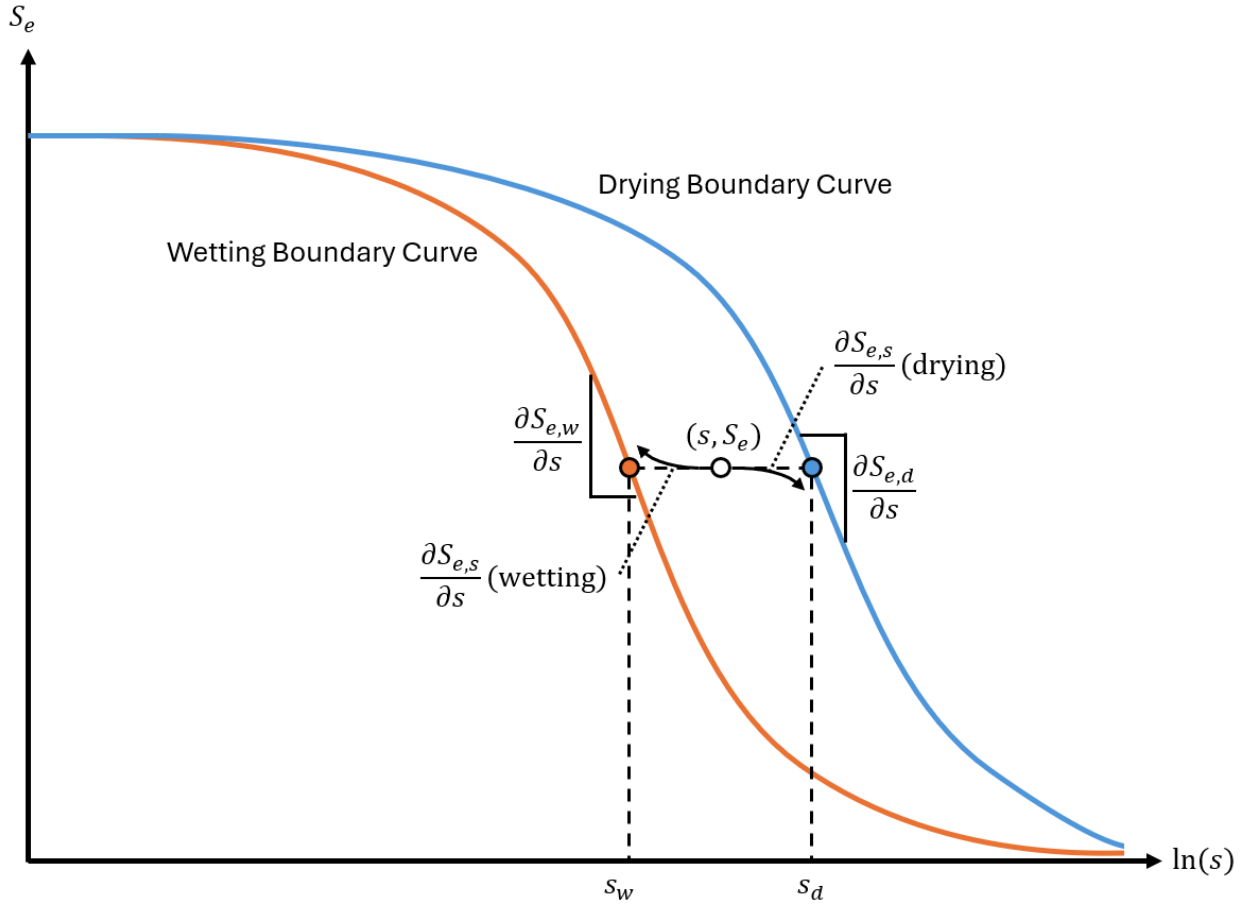

Figure 3: Drying/wetting boundary and scanning curves (modified after [30]).

190 It is clear from this formulation that the increment of suction plays an important role in the
 191 accuracy of the results, as the scanning curve is obtained from the slope, at a given suction,
 192 of the main boundary curve.

193

194 The experimental results with the WRC fitted with the Van Genuchten model are shown
 195 in Figures 4, 5 and 6 for the NAC, RAC and E-M, respectively. In blue is represented the
 196 boundary drying curve and in orange the boundary wetting curve. The experimental data is
 197 shown with markers and their error bars. The Van Genuchten model is proven to accurately
 198 fit the experimental data of our materials.

199 In Figure 7 are shown the results for the hysteresis part of this experiment. Two sets of
 200 hysteresis were measured. The samples were initially dry: they adsorbed water along the

201 boundary wetting curve, then the hysteresis started with 3 desaturation steps followed by
 202 a final re-saturation phase. The model by Zhou et al. (2012) was then fitted based on the
 203 parameters of the boundary curves obtained previously. Each hysteresis resulted in a differ-
 204 ent values for the fitting parameter b , with a small difference between the minimal ($b = 0.75$)
 205 and maximal ($b = 1.2$) values found.

206
 207 A summary of the properties obtained is visible at Table 3. The parameter n_{vG} is rather
 208 constant for a specific composition, and the difference in between compositions is not that
 209 important. For the parameter α_{vG} , which is related to the air-entry pressure, the greater the
 210 maximum pore size of the porous material and the smaller it is in desorption. It is therefore
 211 logical that a mortar has a smaller air-entry pressure than concretes, and that the RAC has
 212 a greater maximum pore size than the NAC. The inverse is true for the sorption.

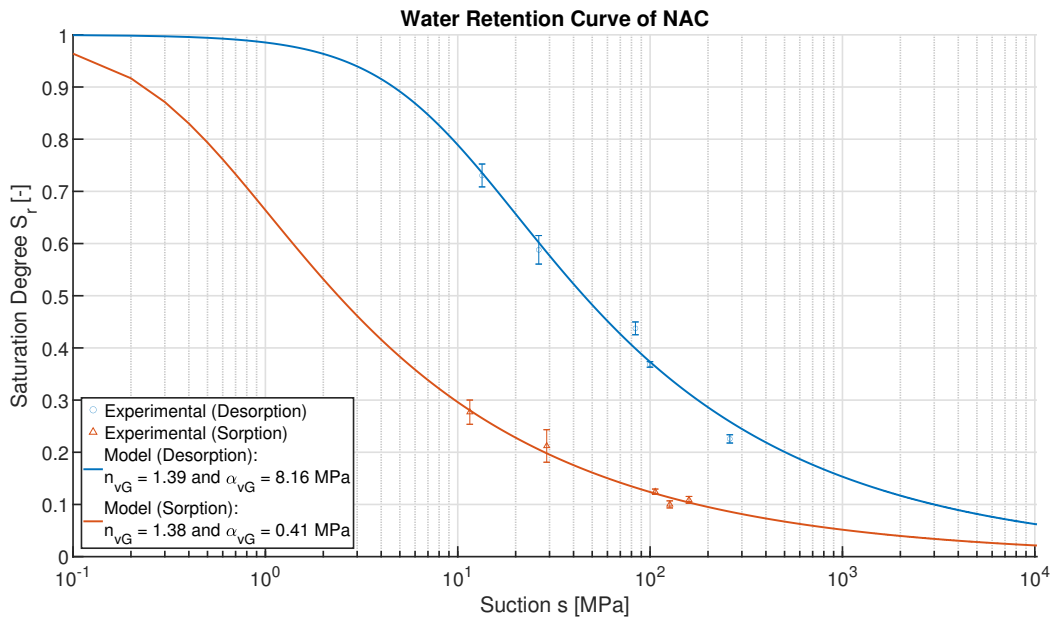

Figure 4: Water Retention Curve of the NAC obtained by fitting the Van Genuchten model to the experimental results of the sorption and desorption experiment.

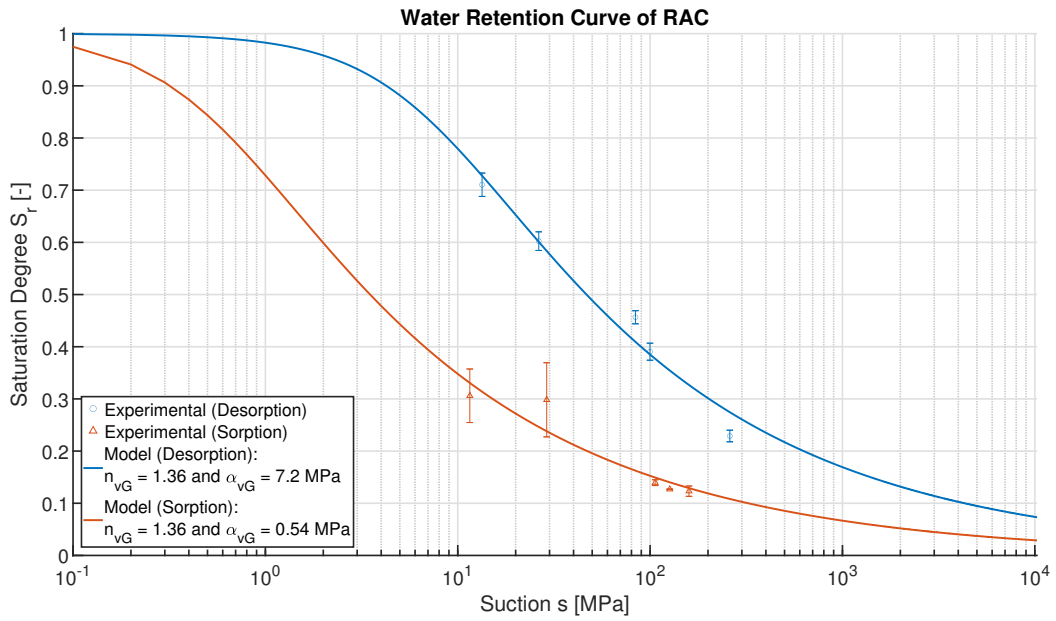

Figure 5: Water Retention Curve of the RAC obtained by fitting the Van Genuchten model to the experimental results of the sorption and desorption experiment.

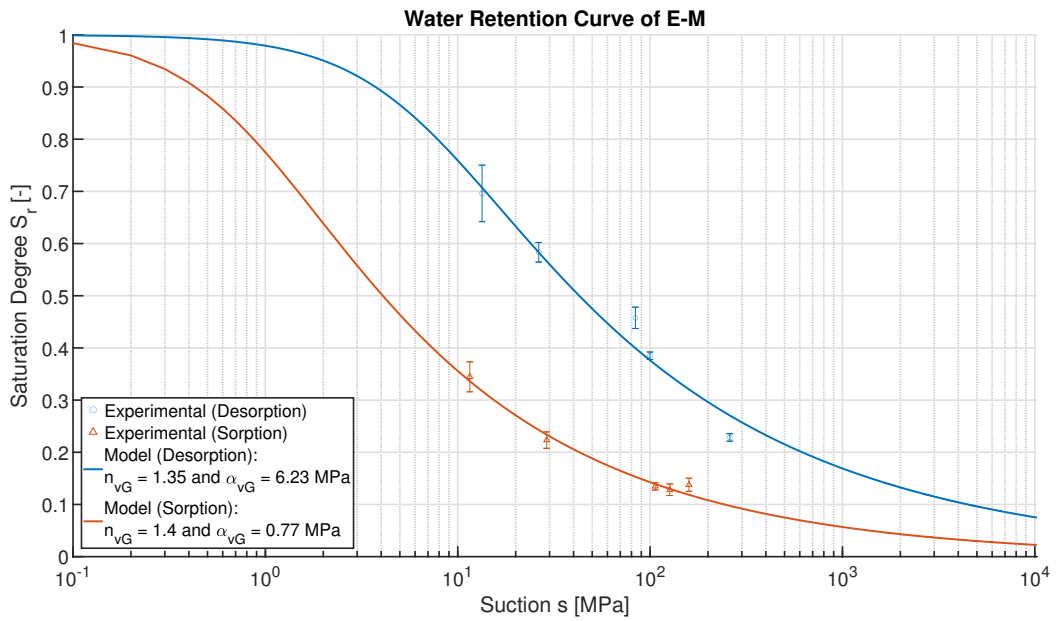

Figure 6: Water Retention Curve of the E-M obtained by fitting the Van Genuchten model to the experimental results of the sorption and desorption experiment.

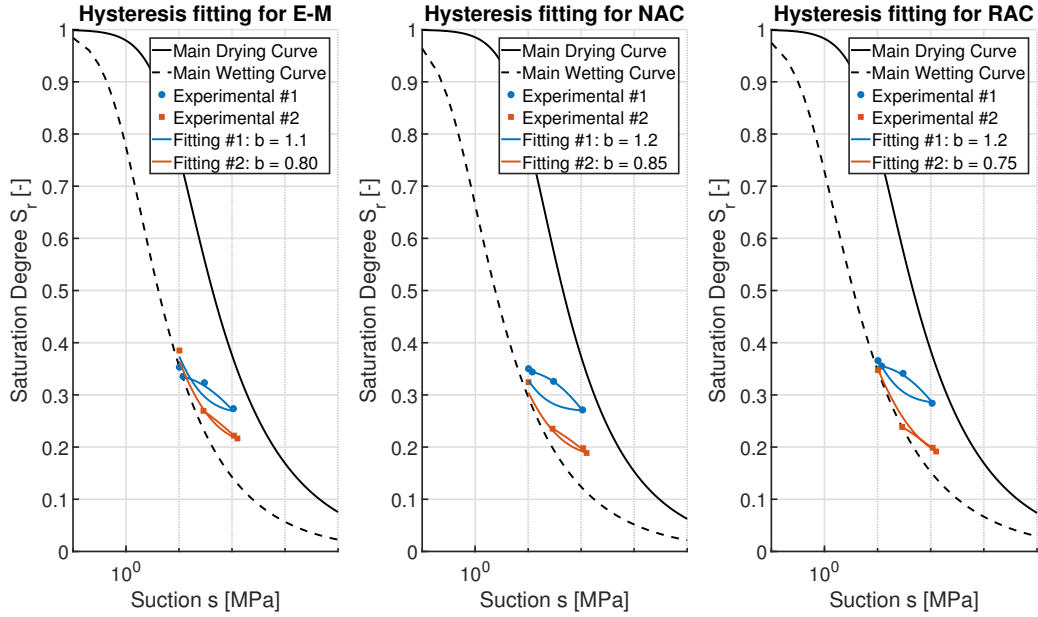

Figure 7: Fitting of the hysteresis of the WRC for all three compositions based on the model by Zhou et al. (2012) [30].

213 3. Numerical Model

214 The numerical model implemented for this work is a multiscale multiphase model based
 215 on the Finite Element Squared (FE²) method. It is implemented in the FE software
 216 LAGAMINE [31] developed at the University of Liège.

217 The multiscale model allows the modelling of water and gas flows, as well as chloride ions
 218 diffusion and advection, inside a saturated or unsaturated porous material, with the subscale
 219 representing a slice of concrete made of mortar (either new mortar or adherent mortar for
 220 the RCA) and impervious natural aggregates, as represented in Figure 8.

221 The model has been proven to be able to replicate experimental results of a concrete based
 222 on intrinsic properties of a mortar, the subscale filling the gap [32].

**Mesh generated by the GMSH software:
5596 nodes and 5068 elements.**

Figure 8: Example of a subscale representing a Recycled Aggregates Concrete for our multiscale numerical model. In blue, the new mortar, and in orange, the adherent mortar. Both may have distinct transfer properties. The natural aggregates, considered impervious with respect to mortar, are unmeshed.

223 A detailed review of the model is available in Fanara et al. (2024) [32]. The constitutive
224 equations at both scales, as well as the algorithm to obtain the subscale, are presented. The
225 parameters implemented in the model are all obtained from the experimental campaign and
226 shown in Table 3.

227 4. Sensitivity Analysis on the Hysteresis

228 The implementation of the hysteresis of the water retention curve requires controlling
229 several variables. These include the parameter b , which influences the gradient of the scan-
230 ning curve [30], and the increment of suction ds , which may introduce estimation errors for

Table 3: Results of the experimental campaign for the three compositions studied: E-M, NAC and RAC.

Parameter	E-M	NAC	RAC
<i>Water absorption experiment</i>			
Dry Density [kg/m ³]	2025	2263	2061
Porosity [% Volume]	22.83	14.16	20.5
<i>Water permeability experiment</i>			
Intrinsic Permeability [10 ⁻¹⁹ m ²]	38.7	1.73	2.58
<i>Static sorption and desorption experiment</i>			
n_{vG} (Desorption) [-]	1.35	1.39	1.36
n_{vG} (Sorption) [-]	1.4	1.38	1.36
α_{vG} (Desorption) [MPa]	6.23	8.16	7.2
α_{vG} (Sorption) [MPa]	0.77	0.41	0.54
Hysteresis b_1 [-]	0.8	0.85	0.75
Hysteresis b_2 [-]	1.1	1.2	1.2
<i>Diffusion under unsteady-state</i>			
D_{app} [10 ⁻¹¹ m ² /s at 29 days]	1.43	1.41	1.65

231 the slope of the scanning curve, as per Equation 8.

232

233 The first parameter is obtained experimentally by fitting, although sorption and de-
 234 sorption experiments can be slow and laborious, particularly when observing hysteresis.
 235 Additionally, the experimental work in this research has demonstrated that a single value
 236 of b may not satisfy the same material, depending on its history. Therefore, it is crucial to
 237 understand the effect of this parameter b on our model's response to characterise its signi-
 238 ficance.

239 The second variable, the increment of suction ds , varies in our simulation due to the applied
 240 boundary conditions. As per Equation 8, the derivative $\partial S_r / \partial s$ is assumed constant over the
 241 increment of suction ds . The model is therefore more prone to error with larger increments,

242 as this assumption only holds for small increments of suction.

243

244 The following two sections examine the impact of each variable. The model employs
245 the parameters listed in Table 3. As the mesoscale is composed of permeable mortar, the
246 implemented mesoscale properties (porosity, intrinsic permeability, and chloride diffusion
247 coefficient) are those of the E-M composition, multiplied by 1.3 to account for the difference
248 between a 2D and 3D model [32]. The water retention curve, however, is considered as
249 a macroscale property. Indeed, the parameters of the WRC mainly depend on the type
250 and size of the pores. In our multiscale model, such small components are not directly
251 modelled, and a homogenisation is thus necessary. Two options were available: define the
252 WRC as mesoscale properties, and use the parameters related to the E-M, or define them as
253 macroscale properties and use the parameters of the concretes directly. The second option
254 was chosen as the first seemed to oversimplify the problem. Therefore, the parameters
255 implemented for the WRC correspond to either NAC or RAC, depending on the mesoscale
256 used. Figure 9 shows the two mesoscale representative volume elements modelled for the
257 NAC and RAC used in this sensitivity analysis. The macroscale represents a 1D sample
258 that is 10cm long (Figure 10).

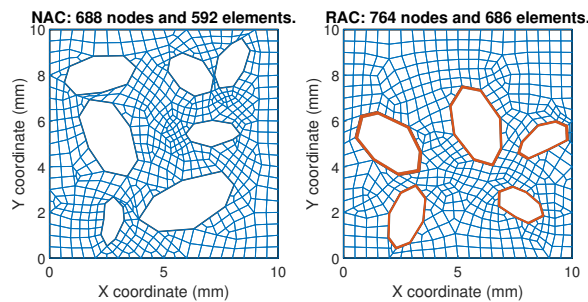

Figure 9: RVE representing the mesoscale of both NAC (left) and RAC (right), with properties of the E-M composition for the blue mortar phase (new mortar matrix) and the same properties for the orange mortar phase (adherent mortar of the RCA).

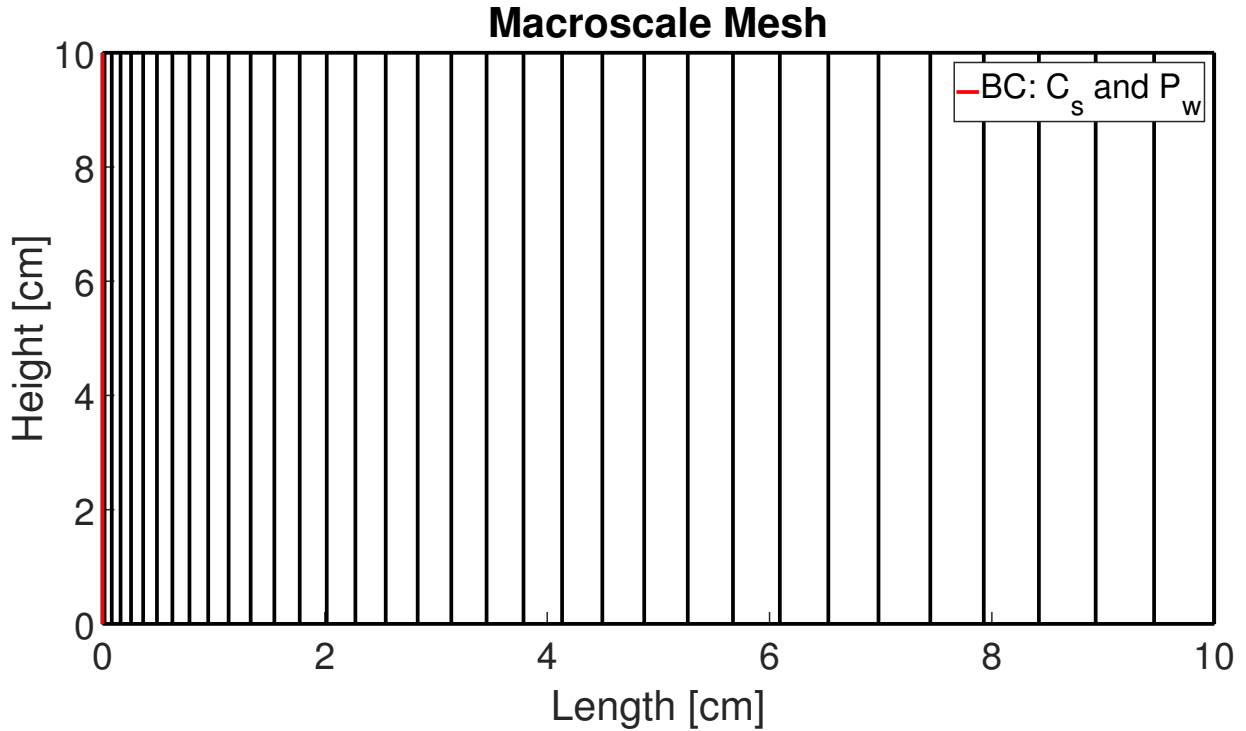

Figure 10: Macroscale mesh for the study of the influence of both the increment of suction and the parameter b on the hysteresis model.

259 4.1. Influence of the Increment of Suction

260 The first sensitivity analysis performed focuses on the increment of suction. A study was
 261 conducted using our multiscale model, and the results are presented in Figure 11. It displays
 262 the solutions of our model to three values of suction increment. Indeed, the increment of
 263 suction calculated from the boundary conditions is divided into sub-increments of equal
 264 value N . The variation in refinement results in a difference in the degree of saturation of the
 265 porous medium, even when the same final suction value is applied as a boundary condition.
 266 The degree of difference may be significant, depending on the size of sub-increments applied.
 267 The reason for this resides in the use of derivatives to navigate the scanning curves, which
 268 are supposed constant over the increment of suction ds . It was therefore chosen to relate the
 269 value of the sub-increment N to the air-entry pressure as it allows for precise results while
 270 maintaining a physical meaning.

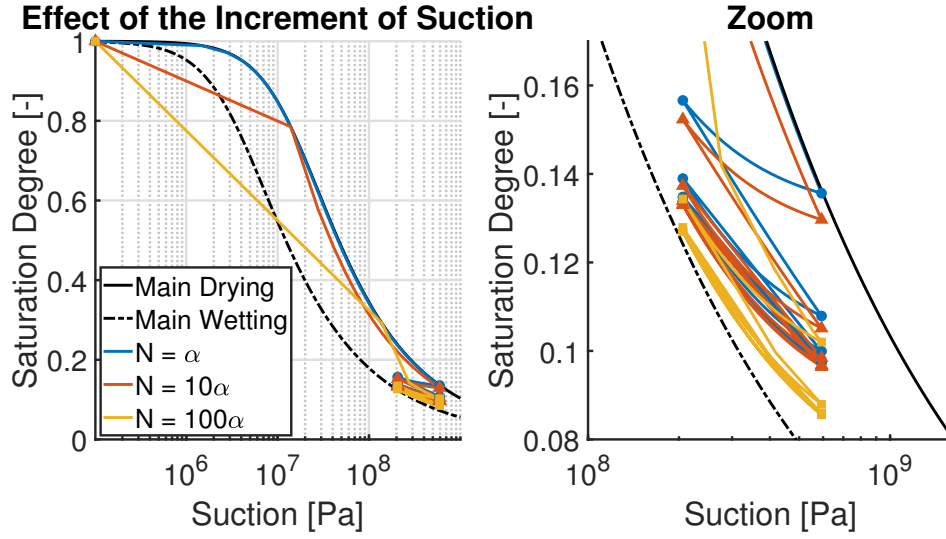

Figure 11: Effect of the increment of suction on the hysteresis model. On the left, the total response for three different values of increment of suction (noted N). On the right, a zoom on the hysteresis part of the response.

271 4.2. Influence of Parameter b

272 The second parameter studied is b , a positive, dimensionless value that controls the slope
 273 of the hysteresis scanning curve. This curve ranges from parallel to the main water retention
 274 curve (b closer to zero) to horizontal (b closer to infinity). Figure 13 displays the results of
 275 our multiscale model for a NAC and RAC RVE, and for various values of b . Two simulations
 276 were conducted without the hysteresis of the water retention curve, using properties of the
 277 boundary drying or wetting curves.

278 The initial water pressure conditions inside the sample were equal to the atmospheric pres-
 279 sure. The pressure on the outside border is changed bi-annually to -2MPa and -200MPa for
 280 a period of ten years. Furthermore, the outside border is set to have a chloride content of
 281 0.11 [-], while the inside of the sample is initially devoid of chloride. The macroscale mesh
 282 and the boundary conditions are shown in Figures 10 and 12.

283 The higher the value of b , the faster the hysteresis reaches the boundary curves. Addi-
 284 tionally, the saturation degree throughout the NAC has a greater variation range than the
 285 RAC RVE.

Figure 12: Boundary conditions for the study of the influence of the parameter b on the hysteresis model.

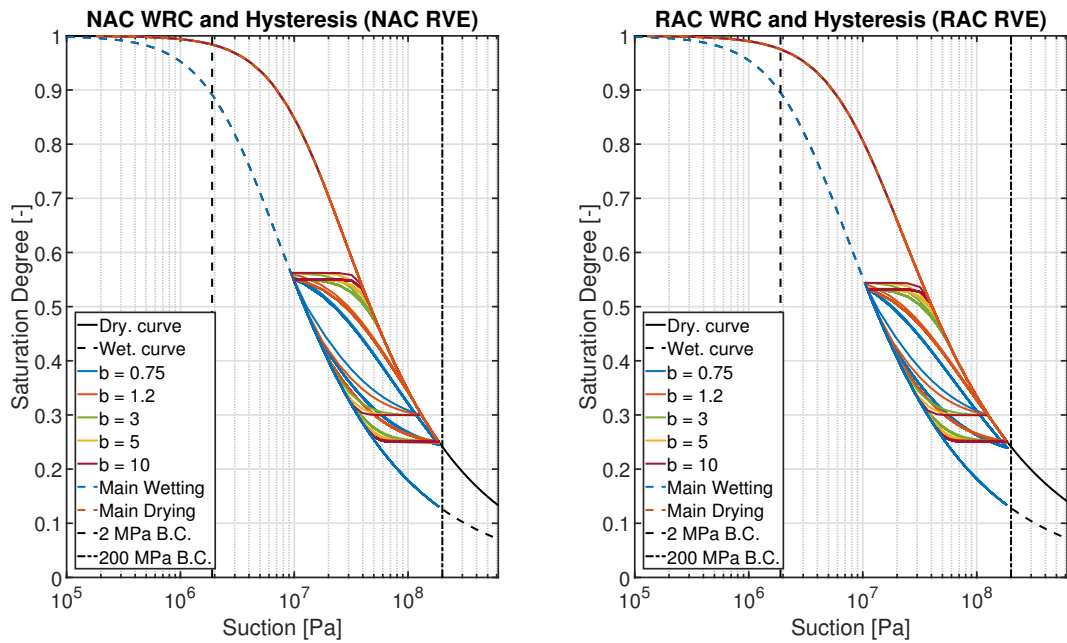

Figure 13: Influence of the parameter b on the hysteresis model: evolution of the saturation degree with the applied suction, for NAC (left) and RAC (right).

286 This is confirmed by Figure 14, which shows the evolution of the saturation degree at the
 287 surface of exchange of the concrete for both the NAC and RAC. It is evident that the hysteresis
 288 curves approach the main boundary curves during both drying and wetting phases. The
 289 transition slope becomes more horizontal with an increase in the value of b , which relates to
 290 a faster convergence of the hysteresis curves to the boundary curves.

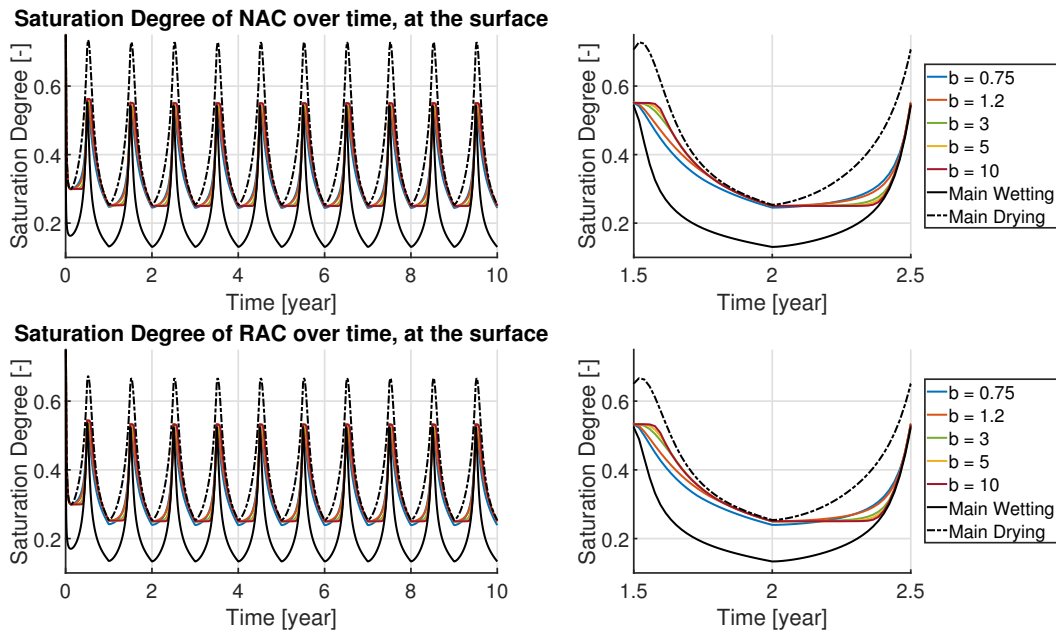

Figure 14: Influence of the parameter b on the hysteresis model: Water Saturation Degree of NAC and RAC at the surface over a ten-year period (left), with a focus on a specific year (right).

291 Figures 15 and 16 show the chloride content evolution at depths of 0cm, 2cm, 5cm, and
 292 10cm inside the sample for both NAC and RAC over a ten-year period. Additionally, the
 293 results are presented in Figure 17 at a depth of 3cm only.

294 As the value of b increases, the variations between drying and wetting phases decrease and
 295 the water saturation degree evolves more linearly. Consequently, the chloride content tends
 296 to be higher for greater values of b , with a negligible difference for values of 3 and above.
 297 Using a higher value of b is therefore conservative due to the overestimation of the chloride
 298 content.

299 Furthermore, the impact of the boundary conditions is smaller at greater depth, the diffusion

300 being predominant over the advection of chloride ions. At the surface, the difference between
 301 the values of b is negligible due to the applied boundary conditions.
 302 Additionally, it may be concluded that higher saturation degrees and chloride contents are
 303 positively correlated, as supported by simulations without hysteresis. Indeed, the sample
 304 with the boundary drying curve consistently exhibits higher chloride content than the one
 305 with the boundary wetting curve.

Figure 15: Influence of the parameter b on the hysteresis model: Chloride Content of NAC at 0, 2, 5 and 10cm depth over a ten-year period.

306 Therefore, it is necessary to implement the hysteresis model to obtain accurate chloride
 307 content values. Otherwise, the chloride content may be underestimated or overestimated
 308 when using the properties of the boundary wetting or drying curve, respectively. Addi-
 309 tionally, it is useful to use the correct value of b , which can be obtained experimentally, to
 310 avoid overestimating the chloride content within the sample. However, if experimental work
 311 is to be excluded, a value of b greater than 3 should be used as it is on the safety side.
 312 Furthermore, the difference in chloride content caused by the different values of b decreases
 313 with time, as represented in Figures 18 and 19, which show the mean chloride content over

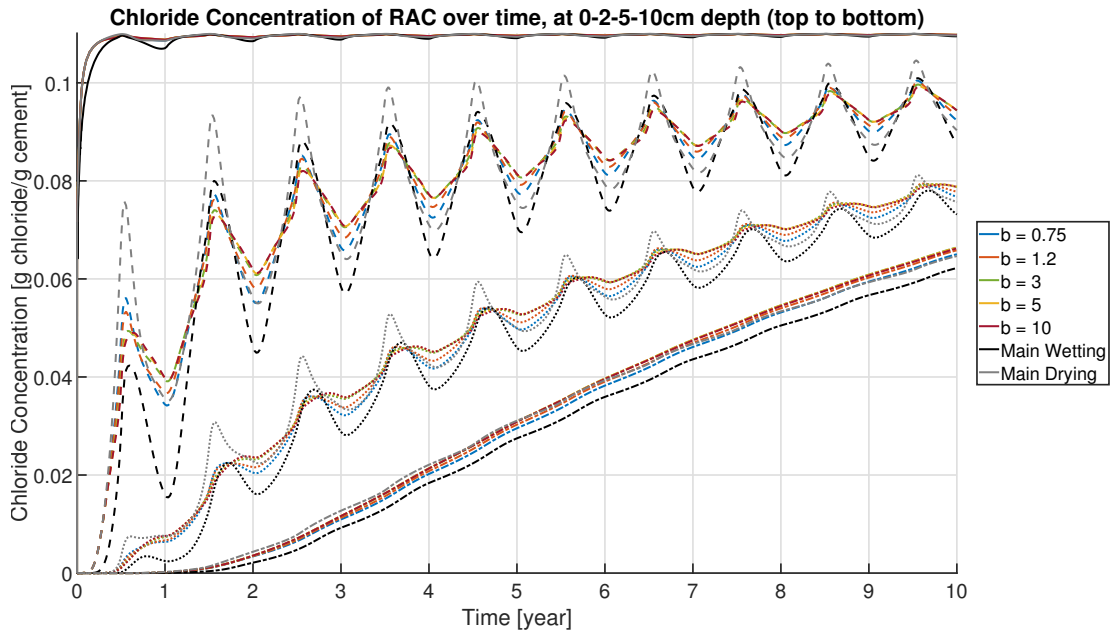

Figure 16: Influence of the parameter b on the hysteresis model: Chloride Content of RAC at 0, 2, 5 and 10cm depth over a ten-year period.

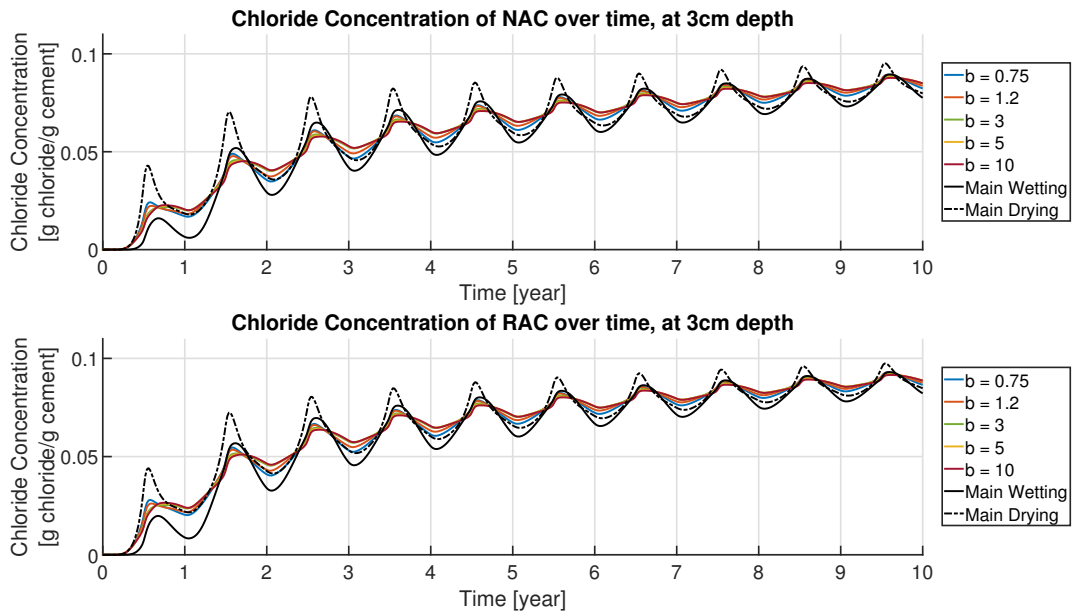

Figure 17: Influence of the parameter b on the hysteresis model: Chloride Content of NAC and RAC at 3cm depth over a ten-year period.

314 the first two centimetres of the sample, after 189 days and 10 years, respectively. One may
 315 see that after 189 days, there is a noticeable difference in between the several values of b .
 316 However, after 10 years, only a slight difference in the mean chloride content for the differ-
 317 ent values of b is visible. However, once again, the usefulness of the implementation of the
 318 hysteresis is confirmed as the results for the boundary curves only are quite different than
 319 with the hysteresis implemented.

Figure 18: Influence of the parameter b on the hysteresis model: mean chloride content over the first 2cm of the sample, after 189 days.

320 5. Conclusion

321 This paper focuses on implementing a hysteresis model for the water retention curves of
 322 concrete. Water retention curves are a useful tool for modelling unsaturated conditions in
 323 porous materials. However, their hysteresis is often neglected when implemented numerically
 324 due to the difficulty of obtaining experimental results for calibration. For the development
 325 of this model, the Van Genuchten model (1980) [24] was implemented for the boundary
 326 drying and wetting curves, along with the hysteresis model by Zhou et al. (2012) [30] that

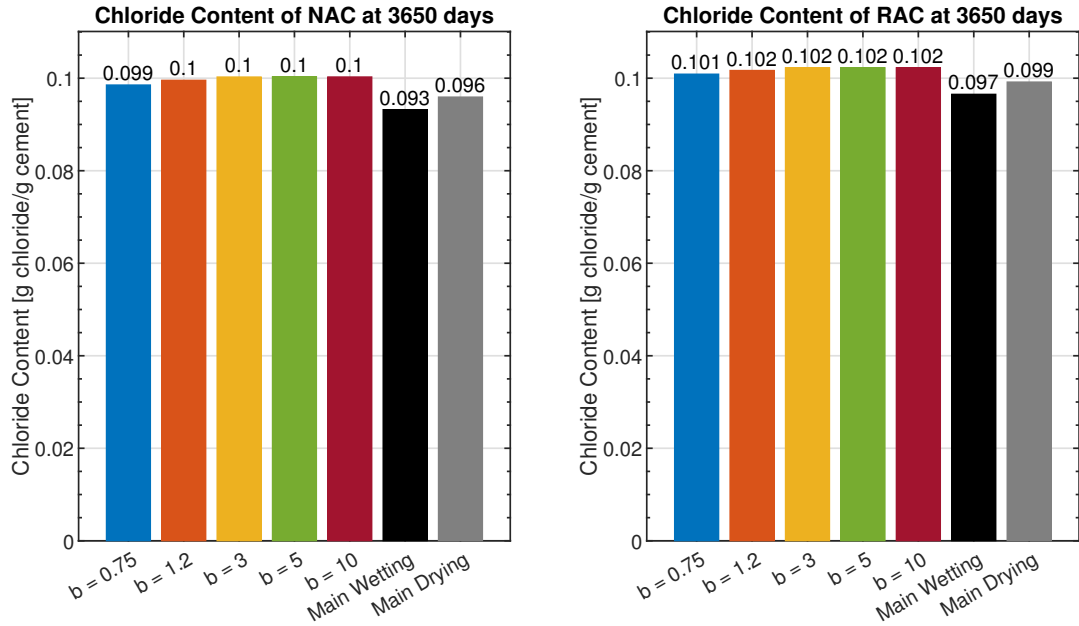

Figure 19: Influence of the parameter b on the hysteresis model: mean chloride content over the first 2cm of the sample, after 10 years.

327 is compatible with the boundary curves of Van Genuchten.

328 Experiments were conducted on concretes made of 100% natural aggregates and recycled
 329 concrete aggregates, as well as on an equivalent mortar. This experimentation allowed
 330 for the determination of numerous parameters necessary for the implemented constitutive
 331 equations. The Van Genuchten model, along with the hysteresis model by Zhou et al., was
 332 experimentally calibrated to accurately replicate unsaturated conditions of concrete made
 333 from natural or recycled aggregates.

334
 335 The model was used for a sensitivity analysis on two parameters: the value of b , the
 336 fitting parameter for the hysteresis model, and the increment of suction ds (Equation 8). It
 337 was necessary to perform experiments to calibrate the value of parameter b as the satura-
 338 tion degree obtained numerically may be erroneous. To better understand the influence of
 339 b , the model allowed for the ingress of chloride ions into the concrete. Chloride ingress is
 340 strongly influenced by the saturation degree of the porous system, making it a useful tool

341 for characterising the impact of the hysteresis. Results have shown that higher values of b
342 correspond to higher chloride content. Therefore, it may be better to use a value of b of 3
343 or higher to err on the side of caution and avoid the need for further experimentation.
344 Regarding the increment of suction (ds), it has been proven to significantly affect the satur-
345 ation degree as per Equation 8. Therefore, it was decided to divide the boundary conditions
346 into sub-increments whose value is equal to the air-entry pressure, which has proven to be
347 sufficient for obtaining accurate results.

348

349 When comparing the results of our study between the NAC and RAC, it was experi-
350 mentally found that the RAC has a smaller (or higher) air-entry pressure for the boundary
351 drying (or wetting) curve. This means that the exchange of moisture with the environment
352 takes place sooner than for the NAC. The parameter n_{vG} , which corresponds to the rate of
353 (de)saturation, is rather similar for both compositions. If we consider the chloride content
354 of the two compositions, the chloride content of the RAC tends to be higher than that of
355 the NAC, which is logical because of the greater movement of water between the sample
356 and its environment, and the greater chloride diffusion coefficient of the RAC.
