## Abstract

**Background** Intracardiac echocardiography (ICE) appears to be a potential alternative for percutaneous left atrial appendage occlusion (LAAO) to transesophageal echocardiography (TEE). Thus, a meta-analysis was performed comparing ICE vs. TEE for LAAO guidance.

**Methods** A comprehensive literature search was performed using MEDLINE, Scopus and Web of Science electronic databases from their inception to November 2023.

**Results** 18 studies (124,230 patients) were included. Technical success was higher in ICE- compared to TEE-guidance (OR: 1.36, 95% CI 1.14 to 1.63,  $p=0.006$ ) and fewer devices employed (SMD: -0.22, 95% CI -0.43 to -0.01,  $p=0.04$ ,  $I^2=62\%$ ). ICE guidance related with more pericardial effusion/tamponade and iatrogenic residual shunts (logRR: 0.62, 95% CI 0.36 to 0.89,  $p<0.001$  and RR: 1.53, 95% CI 1.12 to 2.09,  $p=0.02$ ,  $I^2=1\%$ , respectively). More vascular complications were noted in ICE group (logRR: 0.45, 95% CI 0.11 to 0.78,  $p=0.009$ ).

**Conclusion** ICE-guided imaging is an effective alternative to TEE in LAAO, as it shows better efficacy than TEE, considering technical success. However, the higher rates of adverse events should be carefully considered.

## Introduction

Atrial fibrillation (AF) is the most frequent cardiac arrhythmia worldwide with a prevalence that is expected to increase in proportion among the elderly population over the following decades [1], and accounts for approximately 20–30% of ischemic strokes [2]. In non-valvular AF, nearly 90% of cardioembolic strokes originate from thrombus formation in the left atrial appendage (LAA) [3–5]. Long-term oral anticoagulation (OAC) is currently the standard treatment for stroke prevention in patients with AF, particularly when

there is a high risk of ischemic stroke assessed most frequently using the CHA<sub>2</sub>DS<sub>2</sub>-VASc score [2, 6].

Two randomized controlled studies, PROTECT AF and PREVAIL [7–10], have proven the efficacy of LAA occlusion (LAAO) in preventing AF-related stroke and reducing major bleeding events compared with warfarin. Recent clinical studies demonstrated the non-inferiority of LAAO versus novel OACs in reducing thromboembolic and major bleeding events during long-term follow-up [11, 12]. The 2019 AHA/ACC/HRS guidelines [13] and 2020 ESC guidelines [14] for the diagnosis and management of AF both recommend LAAO to prevent stroke in patients with nonvalvular AF and contraindications to anticoagulation (IIb). LAAO has emerged as a safe and effective alternative preventive treatment to LAA thrombus formation and reduces the risk of thromboembolism among patients with absolute or relative contraindications to anticoagulation treatment [15, 16]. The commonly used devices for LAAO procedures include Watchman and Amplatzer Cardiac Plug (ACP) [17–20].

Pre-procedural planning needed for successful deployment of LAAO devices includes the utilization of cardiac computed tomography angiography (CCTA) and transesophageal echocardiography (TEE) to detect LAA thrombus and identify appendage morphology with the appropriate device sizing. TEE is most commonly utilized in conjunction with fluoroscopy for procedural guidance [21]. TEE has significant drawbacks including the frequent need for general anesthesia or deep sedation and longer procedural times [21]. In recently years, intracardiac echocardiography (ICE) has been proposed as an alternative to TEE for LAAO procedure guidance [22]. Studies comparing TEE with ICE for LAAO are few and most of them are single-center studies with a small number of patients, resulting in limited information about efficacy and safety outcomes. Therefore, the objective of this updated meta-analysis is to evaluate the available data comparing the outcome profile of TEE vs. ICE guidance for percutaneous LAAO.

## Methods

### Data source

We searched MEDLINE, Scopus, and Web of Science electronic databases from their inception to November 2023 for studies comparing ICE vs. TEE in LAAO. The present meta-analysis was performed in accordance with the Cochrane Collaboration and Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) statements and the registered protocol is displayed in the PROSPERO database (CRD42024526878) [23].

### Search strategy

The relevant combinations of the medical subject heading (MeSH) terms used in searches included “atrial fibrillation” AND “left atrial appendage” AND “(closure OR occlusion)” AND “intracardiac echocardiography” AND “transesophageal echocardiography”. Studies were included regardless of their language and year of publication.

### Study selection

Studies were considered eligible if they met the following criteria: [1] human subjects aged  $\geq 18$  years undergoing LAAO under ICE or TEE guidance; and [2] studies compared the use of TEE vs. ICE to guide deployment of LAAO device [3], procedural characteristics and clinical outcomes were compared between the ICE-guided group and the TEE-guided group. Studies involving single-arm studies, case reports, editorials, reviews, and expert opinions, were excluded from the present analysis.

### Data extraction

Two investigators (E. B. and N. P.) independently screened all titles and abstracts, and manually searched the full text versions of all relevant studies that fulfilled the inclusion criteria. The reference lists of the retrieved articles were also independently reviewed. Any discrepancies between the two investigators were resolved by a third investigator (PI). Data on study characteristics, baseline characteristics of included patients, procedural characteristics and complications, and follow-up imaging were extracted for the present analysis.

### Quality assessment of studies

The Newcastle-Ottawa Scale [24] (Table 1) was used to appraise the quality of included studies.

### Primary and secondary outcomes

The primary efficacy outcome was technical success, defined as successful deployment and implantation of the device, using the selected imaging modality. The primary safety outcome was the occurrence of any reported procedure-related and device-related complication. Complications included: pericardial effusion (with and without tamponade), stroke/transient ischemic attack, device embolization, device thrombus, vascular access site complications, all bleeding events (including major bleeding), iatrogenic atrial septal defects (IASDs), and peridevice leaks. Secondary outcomes included procedural characteristics such as procedural time, fluoroscopy time, and the volume of contrast agent used.

## Statistical analysis

A meta-analysis was undertaken to assess variations between guidance provided by ICE and TEE concerning procedure-related parameters, procedural and non-procedural adverse events, and device-related adverse events. Findings are reported as mean differences (MD), standardized mean differences (SMD), odds ratios (OR), risk ratios (RR), or logRR alongside their respective 95% confidence intervals (Cis), as appropriate. In cases of studies that have zero events in one or both groups, a continuity correction was applied (constant 0.5). The degree of heterogeneity among studies was measured using  $I^2$ . Effect sizes were combined using a random-effects model. Significant heterogeneity was deemed present if  $I^2$  values exceeded 50%. In cases of significant between-study heterogeneity, we conducted updated meta-analysis after removal of outlying studies. To explore potential publication bias, a contour-enhanced funnel plot was generated, and Egger's test was conducted. Significance was defined by P values less than 0.05. All meta-analyses were generated using the meta and dmetar packages in R studio v.2023.12.1+402.

## Results

### Search results

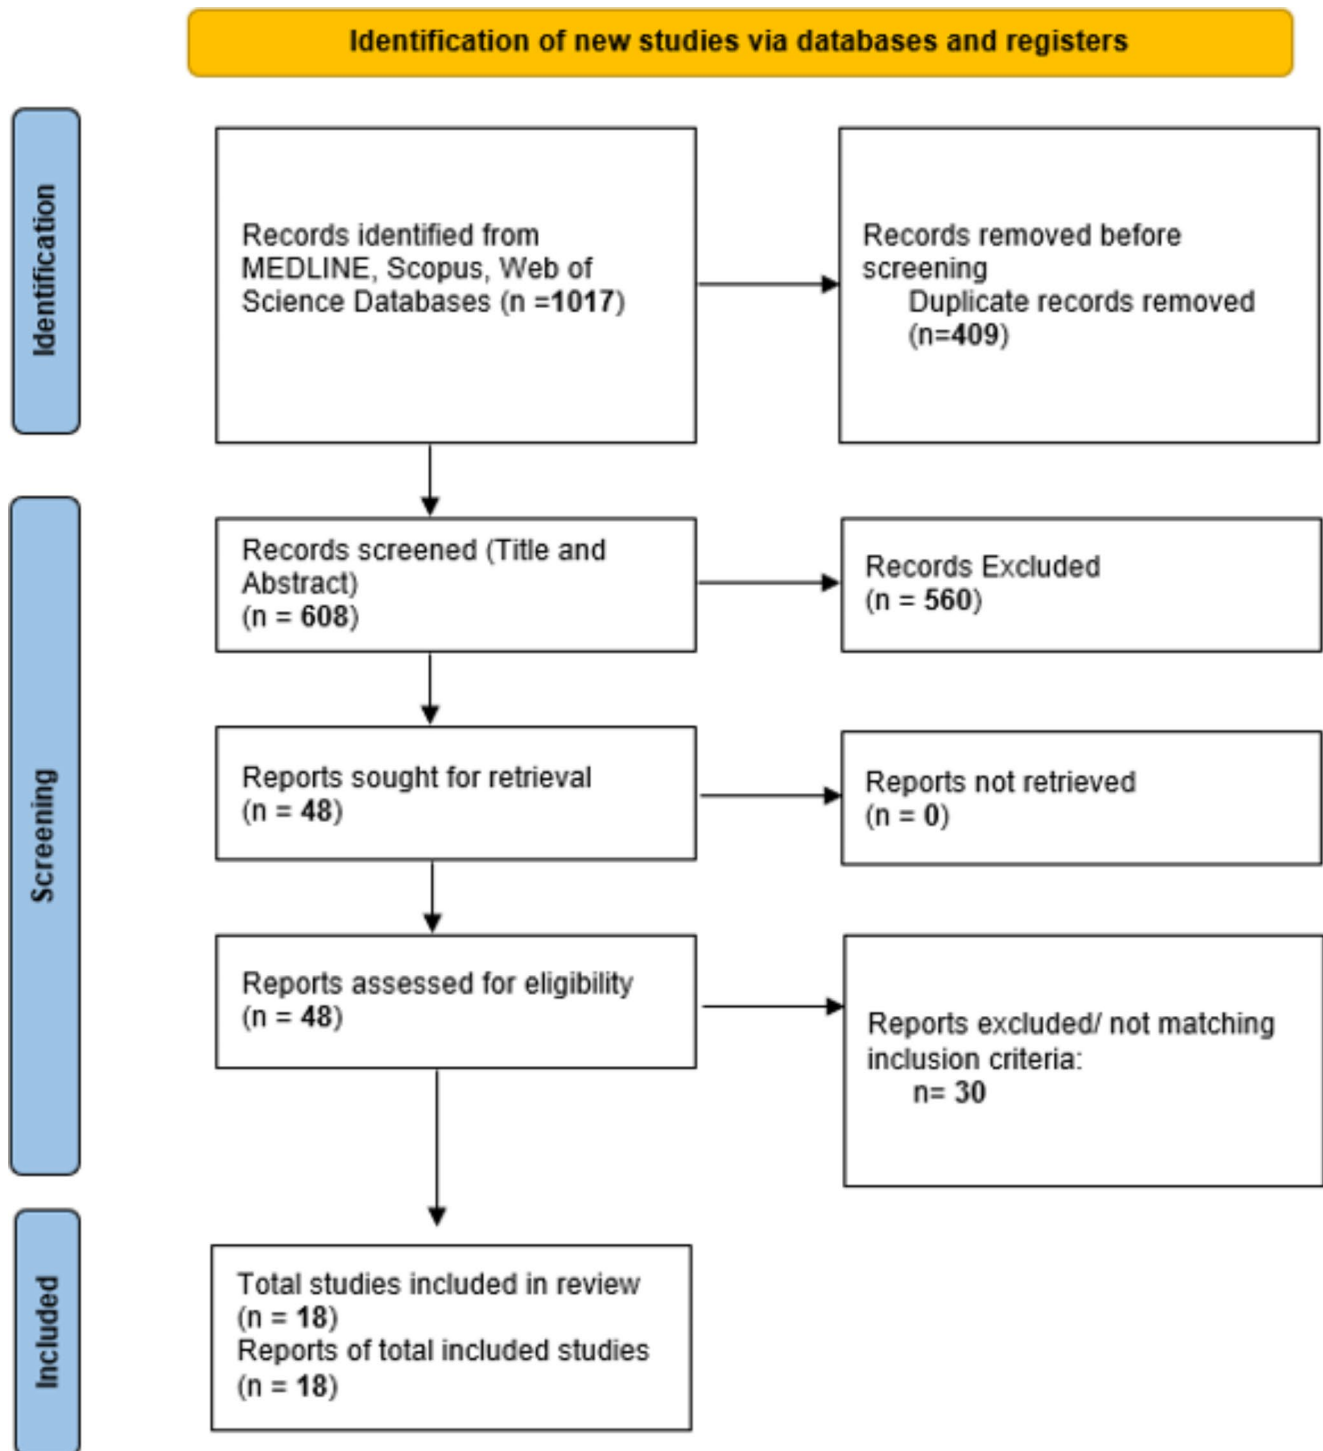

The search yielded initially 1017 records. After removing the duplicates, a total of 608 studies were identified. Next, 560 studies were excluded based on their titles and abstracts and screening of the full texts of the remaining 48 articles resulted in the identification of 18 studies that met all eligibility criteria, as summarized in the PRISMA chart (Fig. 1).

### Study characteristics

This comparative meta-analysis of outcomes in ICE vs. TEE included 124,230 patients (ICE: 5278, TEE: 113297). Table 2 summarizes the study characteristics of the included studies. Follow-up among studies was variable and ranged from time to discharge up to 25 months. Nine studies were single center and eight were multicenter. The study conducted by Iwasawa et al. [25] was not characterized as single or multicenter (Table 2). Six studies were conducted in the USA [26–31], two in Italy [32, 33], two in Portugal [34, 35], one in China [36], one in Denmark [37], one in France [38], one in Korea [39], one in Poland [40], one in Switzerland [41], one was global [42], while one did not specify its location [25].

Eleven studies included Watchman, four included the ACP/Amulet device, four studies included both and two studies included the LAmbré device (Table 2). In two studies, pre-procedural imaging involved either TEE or CCTA, while six studies utilized both imaging modalities. Notably, the studies conducted by Frangieh et al. [41], Iwasawa et al. [25], Hemam et al. [26], Zahid et al. [29], Morcos et al. [30], and Chu et al. [36] did not provide information on pre-procedural imaging, as indicated in Table 2. In all included studies, patients in the TEE-guided group received general anesthesia or sedation, while those in the ICE-guided group did not.

Table 3 summarizes the main baseline characteristics of the patients in the included studies. The mean age of the patients included in the studies ranged from 58 to 88 years. There was no significant difference in mean age (ICE group:  $74.7 \pm 2.17$  years, TEE group:  $75.3 \pm 2.02$  years, p-value: 0.45) or CHA<sub>2</sub>DS<sub>2</sub>VASC score (ICE group:  $4.43 \pm 0.35$ , TEE group:  $4.45 \pm 0.338$ , p-value: 0.73) between TEE and ICE groups.

**Fig. 1** Flowchart of the processing of the included studies

### Primary outcome

### Primary efficacy outcome

**Technical success** We analyzed a total of 12 studies with 37,253 patients (ICE: 3214, TEE: 34039) for differences

in technical success, with higher odds with the use of ICE (OR: 1.36, 95% CI: 1.14, 1.63,  $p=0.006$ ) (Fig. 2, **Panel A**). No evidence of between-study heterogeneity ( $I^2=0\%$ ) was present. Concerning the number of devices used, a meta-analysis of 6 studies indicated that significantly fewer were employed in cases of ICE guidance (SMD: -0.22, 95% CI:

-0.43, -0.01,  $p=0.04$ ,  $I^2=62\%$ ) (Fig. 2, **Panel B**), without any outlying studies.

### Primary safety outcome

**Procedure-related complications** We proceeded to the assessment of LAAO safety by the evaluation of procedure- or device-related adverse events. While there was no difference in procedure- or device-related adverse events in the studies that assessed this combined endpoint (5 studies, RR: 0.98, 95% CI: 0.68, 1.41,  $p=0.86$ ,  $I^2=0\%$ ), the use of ICE was accompanied by a greater risk of pericardial effusion/tamponade (11 studies, logRR: 0.62, 95% CI: 0.36, 0.89,  $p<0.001$ ) (Fig. 3, **Panel A**), with no between-study heterogeneity ( $I^2=0\%$ ). As far as iASDs are concerned, we noted a greater incidence in cases of ICE use (4 studies, RR: 1.53, 95% CI: 1.12, 2.09,  $p=0.02$ ,  $I^2=1\%$ ) (Fig. 3, **Panel B**). More vascular complications were noted in cases of ICE (logRR: 0.45, 95% CI: 0.11, 0.78,  $p=0.009$ ) (Fig. 4, **Panel A**). Interestingly, any bleeding events were met less frequently in cases of ICE use (8 studies, logRR: -0.42, 95% CI: -0.76, -0.07,  $p=0.02$ ,  $I^2=0\%$ ) (Fig. 4, **Panel B**), but major bleeding was equally observed across the two methods (6 studies, logRR: 0.10, 95% CI: -0.09, 0.28,  $p=0.31$ ,  $I^2=0\%$ ) (Fig. 4, **Panel C**).

### Device-related complications

The presence of any PDL was equally noted when using ICE and TEE (8 studies, logRR: -0.09, 95% CI: -0.27, 0.10,  $p=0.36$ ,  $I^2=0\%$ ) (Fig. 5, **Panel A**), with similar findings in cases of significant ( $>5$  mm) PDL (6 studies, logRR: 0.06, 95% CI: -0.47, 0.58,  $p=0.83$ ,  $I^2=0\%$ ) (Fig. 5, **Panel B**). Regarding device-related thrombus, its incidence was less frequent -albeit statistically nonsignificant- in cases of ICE use (7 studies, logRR: -0.24, 95% CI: -0.88, 0.41,  $p=0.48$ ,  $I^2=0\%$ ) (Fig. 5, **Panel C**). Device embolization was

infrequent and was noted similarly in cases of ICE and TEE use (5 studies, logRR: -0.04, 95% CI: -0.93, 0.86,  $p=0.93$ ,  $I^2=0\%$ ) (Fig. 5, **Panel D**).

### Secondary outcomes

#### Procedure-related parameters

We also assessed whether the use of different imaging modalities had any effect on procedure or fluoroscopy time. The meta-analysis of 15 studies (38044 patients) showed no difference between ICE and TEE in procedure time (SMD: -0.14, 95% CI: -0.48, 0.2,  $p=0.42$ ) (Fig. 6, **Panel A**). Due to the significant between-study heterogeneity ( $I^2: 94\%$ ), we conducted an updated meta-analysis after removal of outlying studies (Frangieh et al., Berti et al., Kim et al., and Pommer et al.), with similar findings to the original analysis (SMD: -0.03, 95% CI: -0.20, 0.15,  $p=0.77$ ,  $I^2=76\%$ ). The meta-analysis of 13 studies (3894 patients) did not detect significant variations in fluoroscopy time (SMD: 0.11, 95% CI: -0.15, 0.37,  $p=0.42$ ) (Fig. 6, **Panel B**), while the updated meta-analysis after removal of outlying studies (Grazina et al., Hemam et al., and Nielsen-Kudsk et al.) produced similar observations (SMD: 0.04, 95% CI: -0.18, 0.27,  $p=0.72$ ,  $I^2=84\%$ ). Contrast medium volume did not differ according to the use of ICE or TEE in the original (SMD: 0.02, 95% CI: -0.23, 0.26,  $p=0.89$ ,  $I^2: 87\%$ ) and updated meta-analysis (SMD: 0.01, 95% CI: -0.22, 0.24,  $p=0.93$ ,  $I^2: 76\%$ ).

### Publication bias

The egger's test on the predetermined outcomes (displayed in Supplementary Table 9) yielded nonsignificant results. In line with these observations, inspection of contour-enhanced funnel plots did not reveal asymmetry, confirming an overall low risk of publication bias (Supplementary Figs. 2–8).

## Discussion

### Main findings

This meta-analysis has shown the following key findings: 1) ICE-guided LAAO is associated with higher technical success and a significantly lower mean number of devices used compared to TEE-guided LAAO; 2) No significant differences were observed in total procedural or fluoroscopy time, as well as in contrast medium volume used; 3) A greater incidence of pericardial effusion/tamponade, iASDs and vascular complications were observed in ICE-guided group and 4) No significant differences were noted in device-related adverse events between the ICE-guided and the TEE-guided groups.

Our extensive literature search identified 9 meta-analyses and 4 systematic reviews that demonstrated similar technical success rates with both two imaging modalities without an increase in risk of complications [43–52]. Compared with previous meta-analyses, we included more studies due to the search strategy and eligibility criteria and one additional study (Ferro et al., 2023<sup>41</sup>) may have increased the power to estimate an actual difference between the two imaging modalities as it included a larger number of patients [31].

### Clinical implications

#### Technical success / devices used

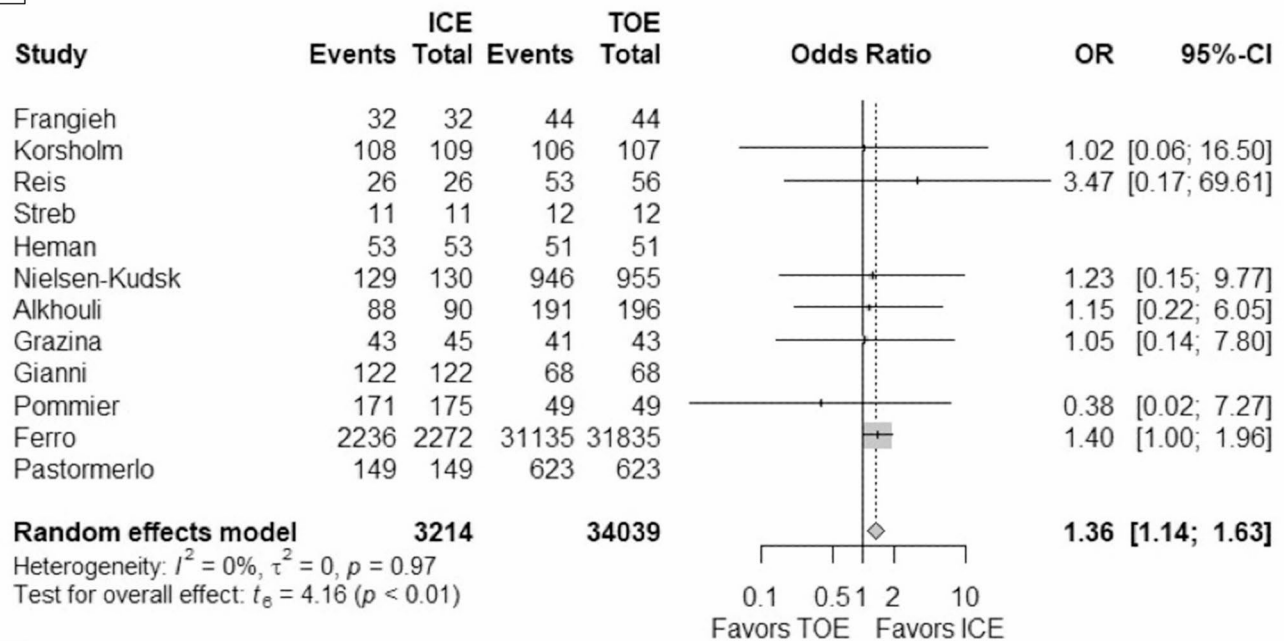

In our meta-analysis, technical success showed higher odds with the use of ICE with a lower mean number of device attempts in cases of ICE guidance. This comes in contrast to commonly reported concerns that ICE imaging may provide

inferior imaging to guide device placement leading to sub-optimal closure [53, 54]. Compared to TEE, ICE allows the operator to directly control the imaging guidance. As a result, a more successful device implantation is achieved even though TEE allows imaging to be guided by another operator enabling them to perform adequate imaging more efficiently. Moreover, ICE in left atrium (LA) position can be utilized in deploying LAAO devices with similar efficacy as TEE as it can provide more clear and detailed imaging of the structure of the LAA due to higher image resolution. However, other factors, including specific anatomical characteristics of the LAA, may influence the safe release of the device. For instance, Korsholm et al. [37] reported a case in the ICE group where a shallow LAA neck, previously identified in the preprocedural CT, resulted in unsuccessful device implantation. Similarly, Reis [34] and Kim [39] noted that technical failures occurred when the LAA was either too small or too large, preventing effective sealing, respectively. Moreover, in studies where complete technical success was not achieved, various factors unrelated to the imaging modality were identified as causes of unsuccessful device implantation. These included technique-related issues, such as a loose connection between the device and the delivery cable [27], as well as the presence of severe venous disease [34].

The reliability of LA ICE for device sizing is also questionable. However, ICE measurements from the right atrium or coronary sinus position correlate well with results from fluoroscopy for LAA sizing and the combination of these measurements offers the operator the ability to accurately choose the appropriate device size [55]. Considering the inherent limitation to size LAA by ICE due to the lack of 3-dimensional capabilities and the high eccentricity of the LAA, patients receiving computed tomography (CT) scan

## A Technical success

## B Devices used

before procedure were found to have less frequent need for a second device in the multicenter study conducted by Berti et al. [55]. Preprocedural CT imaging has been shown to increase both specificity and positive predictive value without compromising sensitivity for LAAO procedural planning [56, 57].

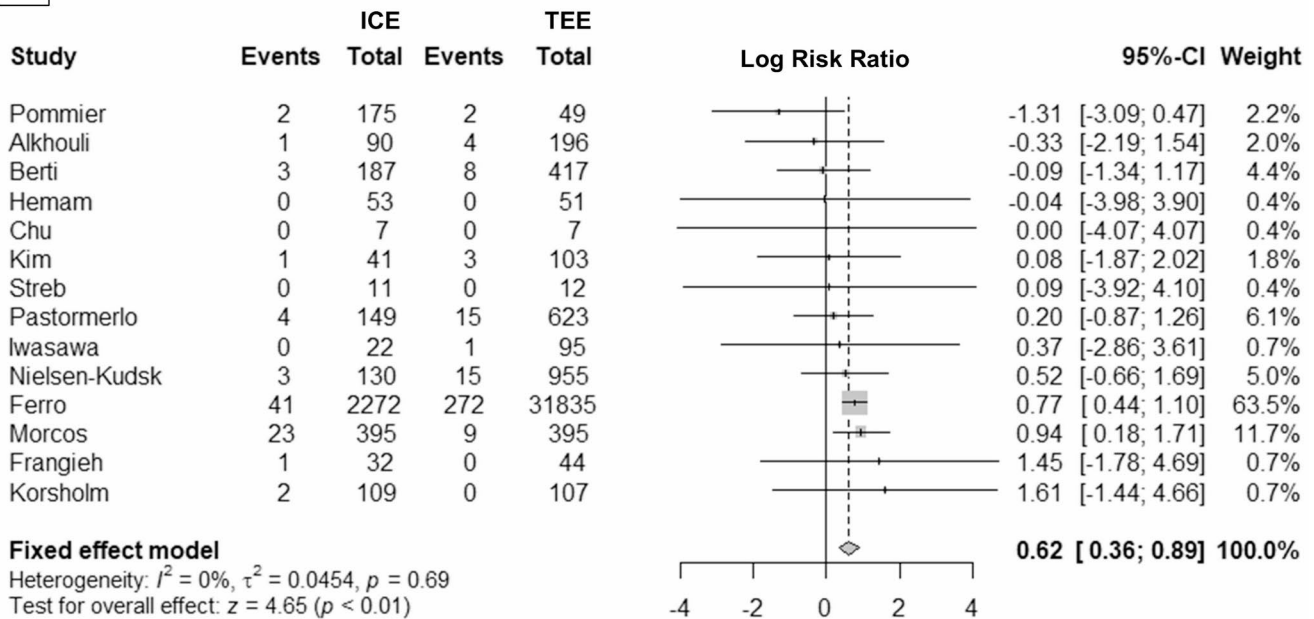

### Pericardial effusion/tamponade

A significantly higher incidence of pericardial effusion or tamponade in the ICE-guided group was found in our analysis. This was not a surprising finding and is consistent with prior reports [32, 58–61] and may be justified by the fact that ICE requires more catheter manipulation to cross the interatrial septum and obtain the target views, increasing the

procedural risk. Piercing the LA or aortic root during transeptal puncture, piercing LA or LAA due to improper catheter manipulation, and tearing the LAA during the device deployment or retraction are among the leading causes of pericardial effusion [62].

Unlike ICE-guided atrial septal closure wherein septal interrogation is performed primarily in the right atrium with little manipulation, LAAO may require maneuvering of the ICE catheter across the interatrial septum within the LA, or within the coronary sinus or left pulmonary artery. Moreover, limited operator experience with LA ICE may also have contributed to the observed differences in pericardial effusion events as a learning curve is required in order to acquire proficiency in LAAO guidance with ICE. Concomitant use of ICE and TEE as operators gain experience with

## A Pericardial effusion/tamponade

## B Iatrogenic ASD

**Fig. 3** Forest plot demonstrating the differences in the incidence of **(A)** pericardial effusion/tamponade and **(B)** iatrogenic atrial septal defect (ASD) between ICE and TEE in LAAC procedures. RR: risk ratio, CI: confidence interval

ICE, training and/or proctoring by physicians experienced with ICE-guided LAAC may also help to minimize the risk of complications during initial experiences with ICE-guided cases.

### Iatrogenic ASDs

A higher prevalence of residual iASDs was also observed with ICE-guided LAAC. This can be explained by both single- and double- puncture techniques used for ICE catheter advancement into the LA, pulmonary artery, or the left superior pulmonary vein [63, 64]. In most studies, a single transeptal puncture was performed and the ICE catheter and the delivery sheath were inserted through the same puncture, further dilating the

puncture site in order to facilitate the passage of the ICE catheter. Also, the additional probe manipulation of the 2-dimensional ICE that is frequently required in order to change views may further increase the size of transeptal hole. These factors may explain the higher risk of iASD seen with ICE in our analysis. Also, the majority of iASDs were depicted at the 45-day follow-up imaging. As most iASDs close spontaneously by 3–12 months, longer-term follow-up is required in order to establish the clinical impact of these residual shunts. Nonetheless, according to the literature on iASDs after AF ablation or transcatheter mitral procedures, their persistence does not result in increased risk of paradoxical embolism or other clinical manifestations [65, 66]. However, the incidence of residual iASDs was poorly investigated in the majority of the included

studies, with a total of four studies assessing iASDS occurrence [27, 34, 35, 37]. Further randomized trials are still needed to confirm these findings by long-term follow-up.

### Vascular complications

We noticed an increased rate of vascular complications in the ICE-guided group. ICE guidance requires an additional venous vascular access site, thus increasing the rate of vascular complications and possibly leading to an increase in hospital stay and costs. Ultrasound-guided venous access and careful maneuvers can reduce access-related complications; however this has to be further tested in future trials.

### Procedural, fluoroscopy times and contrast volume agents

Our meta-analysis showed similar procedural, fluoroscopy times and contrast volume consumption with both techniques. However, significant heterogeneity was evident across studies for these endpoints which may be related to the experience of the operators. Few studies have shown shorter fluoroscopy time, interventional procedure time, and catheterization laboratory time in ICE-guided group compared with TEE [67, 68]. Specifically, in the study conducted by Kim et al. [39], total procedure time was significantly lower in the ICE-guided LAO group, pointing out that placing the ICE probe at the ostium of left superior pulmonary vein offers quite similar image to TEE view. These results are in contrast to a previous report by Frangieh et al. [41] which

showed longer total procedure time in the ICE-guided group compared to TEE, with the learning-curve of the ICE contributing to prolonged procedure time. Similarly, Berti et al. [32] showed longer procedural and fluoroscopy time in the ICE-guided group. Unfortunately, no direct comparison can be performed due to the included heterogeneity of the learning curve of the operators and the different time intervals of the LAAO procedure used along the studies. As the level of the technique and experience is not consistent in each center, the amount of contrast usage is greatly different. Nielson-Kudsk et al. [42] found that ICE-guided procedure takes longer fluoroscopy time and uses more contrast than TEE-guided procedure. Hence, this would be an interesting point for future research as chronic kidney disease is common in the population targeted for LAAO [32, 34, 41, 60].

### Clinical perspectives

Although expert consensus documents are starting to emerge, standardized ICE imaging protocols are needed to disseminate best practices that can improve both periprocedural effectiveness and safety. Also, preprocedural CT scans may help to facilitate navigation and improve safety, while the introduction of 4D ICE may markedly decrease the need for catheter manipulation in the LA. The availability of newer, softer catheters may further promote safety among operators as they become familiar with the ICE technology.

Newer TEE models (with 3D capabilities) are also introduced into the market allowing TEE to be more regularly conducted with deep sedation instead of general anesthesia in many centers [69]. Hence, the cost-effectiveness considerations of ICE and TEE will continue to evolve over time and require further study [22, 26, 29, 30].

### Limitations

The results of this study should be interpreted with caution in the context of the following limitations. The studies included in this meta-analysis were non-randomized and observational in design, which predisposes our analysis to selection or misclassification bias given the variability in inclusion and exclusion criteria of individual studies. Furthermore, this is a study-level meta-analysis, and therefore should be interpreted under its limitations. Additionally, this meta-analysis includes studies with mostly small sample sizes which may affect the stability of the result indicators, reduce the efficiency of the test, and introduce potential research bias. We also included retrospective studies which may be subjected to confounding bias. Also, as most of the data of our analysis are derived from non-granular databases, evaluating the technical success rate is fairly challenging. Besides, due to the variability in post-procedural follow-up timing and the lack of sufficient data, analyzing the

impact of device type and size on PDL proved difficult. Finally, the learning curve and health costs may have affected the use of ICE. Variability in studies is further complicated by operator experience which also contributes to selection bias towards TEE as ICE is a relatively novel technology. A prospective, multicenter, randomized, well-controlled study is needed to clarify the clinical outcomes of LAAO with the comparison of ICE vs. TEE monitoring.

### Conclusion

In conclusion, although TEE remains the gold standard imaging modality during LAAO, the present meta-analysis shows that ICE compared to TEE is associated with higher technical success and a significantly lower mean number of devices used. However, ICE was associated with a higher prevalence of residual iASDs, pericardial effusions and vascular complications. These results suggest that well-designed studies are currently needed to compare safety and efficacy of these imaging modalities during LAAO.
